SEMICONDUCTOR DEVICE HAVING A PLANARIZING FILM FORMED IN A REGION OF A STEP PORTION

TECHNICAL FIELD

The present invention relates to methods for manufacturing semiconductor devices, and semiconductor devices.

BACKGROUND ART

In recent years, as a technique relating to display apparatuses, a so-called monolithic liquid crystal display (hereinafter also referred to as a "system liquid crystal display") has attracted attention in which peripheral device units, such as a drive circuit unit, a control circuit unit, and the like, are integrated with a pixel unit. In a semiconductor device used in such a system liquid crystal display, a switching element for the pixel unit, and the peripheral device unit are simultaneously formed on the same substrate, whereby the number of parts can be significantly reduced. Moreover, steps of assembling and inspecting the liquid crystal display can be reduced. Therefore, the manufacturing cost can be reduced, and the reliability can be improved.

For display apparatuses such as liquid crystal display apparatuses and the like, there is a strong demand for higher performance, such as lower power consumption, and higher definition and a faster response time of image display. There is also a demand for smaller space occupied by the peripheral device unit, and integration of higher-level systems (a memory, a signal processing circuit, etc.).

Therefore, for semiconductor devices used in display apparatuses, there is a strong demand for a still smaller size of each element, and the peripheral device unit requires submicrometer design rules, i.e., fine pattern accuracy at the integrated circuit (hereinafter also referred to as "IC") level so that a larger number of elements are formed in a limited area. For semiconductor elements constituting the peripheral device unit, there is also a demand for a higher mobility of carriers in a semiconductor layer. To meet this demand, the reduction in size of each element is also required.

However, in conventional manufacturing processes which form a semiconductor device directly on a glass substrate, the insufficient heat resistance of the glass substrate may lead to a distortion in the glass substrate in a thermal treatment of the manufacturing process, and therefore, a desired submicrometer circuit pattern may not be formed. Glass substrates used in manufacture of liquid crystal display apparatuses, such as system liquid crystal displays and the like, are becoming larger, resulting in an in-plane distortion in the glass substrate being more likely to occur during the manufacturing process.

In contrast to this, there is a technique of using a silicon-on-insulator (SOI) substrate in which an integrated circuit is formed in a monocrystalline silicon layer provided on an electrical insulator, and transferring a peripheral device unit onto a substrate of a liquid crystal display. With this method, conventional IC chip fabricating processes can be used to form an integrated circuit including semiconductor elements. Therefore, a semiconductor device including a minute and high-performance integrated circuit which has a desired submicrometer circuit design can be achieved. However, when the peripheral device unit is transferred onto the substrate, then if a surface of the substrate on which the transfer is performed is not flat, it is difficult to reliably attach the peripheral device unit to the substrate.

To address such a problem, as described in, for example, Patent Document 1, a technique has been studied and devel-

2

oped for forming gate electrodes of the pixel unit, removing an insulating film and a sacrificial film, by etching, from a region in which a peripheral device unit is to be provided, and attaching a semiconductor device having semiconductor elements to the region. With this technique, the microroughness of the glass surface is reduced by performing etching using an etchant which provides a selectivity ratio with respect to the glass substrate when the sacrificial film is removed. Moreover, it is considered that the bonding strength after the transfer is satisfactorily high compared to a process in which the sacrificial film is not formed (only the insulating film is removed by etching to expose the glass surface).

Patent Document

PATENT DOCUMENT 1: Japanese Patent Laid-Open Publication No. 2004-158821

SUMMARY OF THE INVENTION

Technical Problem

However, in the aforementioned method of forming gate electrodes of a pixel unit, removing an insulating film and a sacrificial film, by etching, from a region in which a peripheral device unit is to be provided, and attaching a semiconductor device including semiconductor elements to the region, it is necessary to provide a step of forming the sacrificial film, resulting in a problem with manufacturing efficiency. Moreover, after the etching, warpage of the glass substrate is likely to occur due to residue or the like of the sacrificial film on the glass surface, or a thermal treatment, resulting in an adverse influence on the bonding strength between the glass substrate and the peripheral device unit.

Solution to the Problem

The present invention has been made in view of the aforementioned problems. It is an object of the present invention to provide a semiconductor device manufacturing method and a semiconductor device which have a satisfactorily high manufacturing efficiency and bonding strength between the substrate and the peripheral device unit.

A method according to the present invention is for manufacturing a semiconductor device including a thin film device unit including a TFT, and a peripheral device unit provided around the thin film device unit and including a semiconductor element. The method includes a first step of preparing a substrate, a second step of bonding the peripheral device unit directly to the substrate, and a third step of forming the thin film device unit on the substrate to which the peripheral device unit is bonded.

A semiconductor device according to the present invention includes a substrate having an insulating surface, a thin film device unit provided on the substrate, and a peripheral device unit provided on the substrate around the thin film device unit, and including a semiconductor element. The peripheral device unit is provided directly on the insulating surface of the substrate.

With such a configuration, the peripheral device unit is bonded directly to the glass substrate, and therefore, there is not a film or the like between the flat glass substrate and the peripheral device unit. Therefore, the glass substrate and the peripheral device unit are satisfactorily attached to each other. Moreover, because a sacrificial film or the like is not formed

on the glass substrate, the manufacturing efficiency of the device is satisfactorily high. Moreover, because the peripheral device unit is bonded to the glass substrate before the thin film device unit is formed, there is not residue of a sacrificial film or the like on the glass substrate before the peripheral device unit is bonded to the glass substrate, and therefore, warpage due to a thermal treatment or the like does not occur. Therefore, the peripheral device unit can be bonded to a flatter surface of the glass substrate. As a result, the glass substrate and the peripheral device unit are more satisfactorily attached to each other.

Advantages of the Invention

According to the present invention, it is possible to provide a semiconductor device manufacturing method and a semiconductor device in which the manufacturing efficiency, and the bonding strength between the substrate and the peripheral device unit are satisfactorily high.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a cross-sectional view of a glass substrate according to a first embodiment on which an alignment mark is formed.

FIG. 2 is a cross-sectional view of the glass substrate to which a peripheral device unit is bonded.

FIG. 3 is a cross-sectional view of the glass substrate on which a gate insulating film is formed.

FIG. 4 is a cross-sectional view of the glass substrate on which a gate electrode is formed.

FIG. 5 is a cross-sectional view of the glass substrate on which a protective film is formed.

FIG. 6 is a cross-sectional view of the glass substrate on which base coat layers, a gate insulating film, and a protective film on a boundary portion between a display region and the peripheral device unit and on the peripheral device unit are removed by etching.

FIG. 7 is a cross-sectional view of the glass substrate on which a TEOS film is formed.

FIG. 8 is a cross-sectional view of the glass substrate on which contact holes are formed.

FIG. 9 is a cross-sectional view of an element substrate according to the first embodiment.

FIG. 10 is a cross-sectional view of a liquid crystal display apparatus according to the first embodiment.

FIG. 11 is a cross-sectional view of a glass substrate according to a second embodiment on which an alignment mark is formed.

FIG. 12 is a cross-sectional view of the glass substrate to which a peripheral device unit is bonded.

FIG. 13 is a cross-sectional view of the glass substrate on which a gate electrode is formed.

FIG. 14 is a cross-sectional view of the glass substrate on which a SiN film is formed.

FIG. 15 is a cross-sectional view of the glass substrate on which a planarizing film is formed.

FIG. 16 is a cross-sectional view of the glass substrate on which the planarizing film is etched.

FIG. 17 is a cross-sectional view of an element substrate according to the second embodiment.

DESCRIPTION OF EMBODIMENTS

Embodiments of the present invention will be described hereinafter with reference to the accompanying drawings. Note that the present invention is not limited to the embodiments below.

First Embodiment

FIGS. 1-10 show a first embodiment of the present invention. FIG. 10 is a diagram schematically showing a main portion of a liquid crystal display apparatus 10. FIG. 9 is an enlarged view of a main portion of an element substrate 11. FIGS. 1-9 are cross-sectional views for describing a method for manufacturing the element substrate 11 which is a semiconductor device.

As shown in FIG. 10, the liquid crystal display apparatus 10 includes the element substrate 11, a counter substrate 12 facing the element substrate 11, and a liquid crystal layer 13 formed therebetween.

As shown in FIG. 9, the element substrate 11 includes a thin film device unit 20. The thin film device unit 20 of the element substrate 11 includes a plurality of pixels (not shown), and thin film transistors (TFTs) 21 which are display elements formed for the respective pixels. An alignment film 14 is provided on a surface closer to the liquid crystal layer 13 of the element substrate 11, while a polarizing plate 15 is stacked on a surface farther from the liquid crystal layer 13 of the element substrate 11. A peripheral device unit 40 which drives and controls the TFTs 21 is provided on the element substrate 11 around the thin film device unit 20.

A color filter, a common electrode made of ITO, and the like are formed on the counter substrate 12, though not shown. Moreover, an alignment film 16 is provided on a surface closer to the liquid crystal layer 13 of the counter substrate 12, while a polarizing plate 17 is stacked on a surface farther than the liquid crystal layer 13 of the counter substrate 12. The liquid crystal layer 13 is enclosed by a sealing member 18 interposed between the element substrate 11 and the counter substrate 12. In the liquid crystal display apparatus 10 thus configured, the TFTs 21 are used to control the aligned states of liquid crystal molecules in the liquid crystal layer 13 to provide desired display.

The TFTs 21 are formed on a glass substrate 22 with base coat layers 24 and 25 being interposed therebetween. The glass substrate 22 is preferably made of barium-borosilicate glass, barium-aluminoborosilicate glass, alkaline earth-aluminoborosilicate glass, borosilicate glass, alkaline earth-zinc-lead-aluminoborosilicate glass, alkaline earth-zinc-aluminoborosilicate glass, or the like. The TFTs 21 each include a semiconductor layer 23 having an active region, a gate insulating film 26 covering the semiconductor layer 23, a gate electrode 27 provided on the gate insulating film 26, and a protective film 28 covering the gate electrode 27. The semiconductor layer 23 has a channel region 23c, lightly doped drain (LDD) regions 23s' and 23d' (both low-concentration impurity regions) formed on opposite sides of the channel

5

region **23c**, and a source region **23s** and a drain region **23d** (both high-concentration impurity regions) between which the channel region **23c** and the LDD regions **23s'** and **23d'** are interposed. The semiconductor layer **23** is an amorphous silicon semiconductor layer or a polycrystalline silicon semiconductor layer.

As shown in FIG. 9, the peripheral device unit **40** is formed on a surface of the glass substrate **22** at a position corresponding to an alignment mark **41**. The peripheral device unit **40** includes a MOS transistor **42** which is a semiconductor element. An insulating film **43** which is a first planarizing film, an interlayer insulating film **44** which is a second planarizing film, an interlayer insulating film **45**, and an insulating film **46** are stacked in this stated order on the glass substrate **22**. The insulating film **43** is attached to the surface of the glass substrate **22**.

A surface of the insulating film **46** in the peripheral device unit **40** is concave toward the glass substrate **22**. A gate oxide film **47** and a LOCOS oxide film **48** are formed on the surface of the insulating film **46**. A gate electrode **49** and sidewalls **50** are formed between the gate oxide film **47** and the insulating film **46**. The sidewalls **50** are formed on left and right side surfaces of the gate electrode **49**, respectively.

A source electrode **51s** and a drain electrode **51d** are formed in the insulating film **43** at a boundary between the insulating film **43** and the interlayer insulating film **44**.

A semiconductor layer **52** which is a monocrystalline silicon layer is formed on a surface of the gate oxide film **47**. The semiconductor layer **52** is formed by forming a release layer by ion-implanting a release material into a semiconductor substrate, and then separating and removing a portion of the semiconductor substrate along the release layer.

An active region **53** is formed in the semiconductor layer **52**. The active region **53** includes a channel region **53c**, LDD regions (low-concentration impurity regions) **53c'** and **53d'** formed on left and right sides of the channel region **53c**, respectively, and source and drain regions (high-concentration impurity region) **53s** and **53d** formed farther outside than the LDD regions **53c'** and **53d'**, respectively. The LDD regions **53c'** and **53d'** and the source and drain regions **53s** and **53d** are doped with, for example, an N-type impurity, such as phosphorus or the like.

The channel region **53c** faces the gate electrode **49** via the gate oxide film **47**. The LDD regions **53c'** and **53d'** face the respective sidewalls **50** via the gate oxide film **47**. The source electrode **51s** is connected to the source region **53s** via a contact hole **54s**, while the drain electrode **51d** is connected to the drain region **53d** via a contact hole **54d**.

A TEOS film **55**, a SiN film **56**, and a TEOS film **57** are formed as insulating films on the protective film **28** of the TFT **21** and the semiconductor layer **52** of the peripheral device unit **40**. Contact holes **58s** and **58d** are formed which penetrate the TEOS film **55**, the SiN film **56**, the TEOS film **57**, the protective film **28**, and the gate insulating film **26** to reach the source region **23s** and the drain region **23d** of the semiconductor layer **23**, respectively. A contact hole **59s** is formed which penetrates the TEOS film **55**, the SiN film **56**, the TEOS film **57**, the LOCOS oxide film **48**, the interlayer insulating film **44**, the interlayer insulating film **45**, and the insulating film **46** to reach the source electrode **51s** of the peripheral device unit **40**. Interconnection portions **60d**, **60s**, and **61s** made of a conductive material are formed in the contact holes **58d**, **58s**, and **59s**, respectively.

A passivation film **62** is formed to cover the interconnection portions **60d**, **60s**, and **61s** of the TFT **21** and the peripheral device unit **40**. A resin film **63** made of an organic resin, an inorganic resin, a polyimide, or the like is formed as a

6

planarizing film on the passivation film **62**. A region where the resin film **63** is not formed is formed on each of the interconnection portions **60s** and **61s**, and a conductive film **64** made of ITO or the like is formed which extends over the region and a part of the resin film **63**. The peripheral device unit **40** and the TFT **21** are electrically connected to each other via the conductive film **64**.

Method for Manufacturing Device Substrate **11**

Next, a method for manufacturing the element substrate **11** of the liquid crystal display apparatus **10** will be described.

Initially, as shown in FIG. 1, the glass substrate **22** is prepared, and the alignment mark **41** is formed on a surface thereof, which is used for positioning when the peripheral device unit is formed. The alignment mark **41** may be formed by cutting the glass substrate **22**, or by printing a resin material on the glass substrate **22**.

In a separate step, the peripheral device unit **40** which is to be bonded to the glass substrate **22** is produced. Here, a method for manufacturing the peripheral device unit **40** will be described. Initially, a P-well region, and the LOCOS oxide film **48** and the gate oxide film **47** are formed in the semiconductor substrate which is a silicon substrate (corresponding to the semiconductor layer **52** before a portion thereof is separated).

Specifically, a thermal oxide film is formed on the semiconductor substrate, a P-type impurity element (e.g., boron) is ion implanted into the semiconductor substrate. Next, the semiconductor substrate is subjected to a thermal treatment so that the ion-implanted P-type impurity element is diffused and activated, thereby forming the P-well region.

Next, a silicon nitride film is formed and patterned on a surface of the thermal oxide film, and thereafter, the thermal oxide film and the semiconductor substrate are subjected to LOCOS oxidation, to form the LOCOS oxide film **48** on left and right sides of the silicon nitride film. Next, initially, the silicon nitride film and the thermal oxide film are removed, and thereafter, a thermal oxide film and the like are formed.

Next, a film made of a conductive material is stacked on a surface of the gate oxide film **47**, and is then patterned by a photolithography method or the like, to form the gate electrode **49** on the semiconductor substrate.

Next, the active region **53** is formed in the P-well region of the semiconductor substrate. Initially, an N-type impurity element such as phosphorus or the like is ion implanted to form the N-type LDD regions **53c'** and **53d'**. Next, a SiO₂ film is formed on a surface of the gate oxide film **47** by CVD or the like, and is then subjected to etching, to form the sidewalls **50** on the opposite sidewalls of the gate electrode **49**.

Next, an N-type impurity element such as phosphorus or the like is ion implanted using the gate electrode **49** and the sidewalls **50** as a mask to form the N-type source and drain regions **53s** and **53d**. Thereafter, the insulating film **46** made of SiO₂ or the like is formed, and thereafter, the LDD regions **53c'** and **53d'**, the source region **53s**, and the drain region **53d** are subjected to a thermal treatment to activate the ion-implanted impurity element.

Next, the interlayer insulating film **45** is formed on a surface of the insulating film **46**, and thereafter, a release material including H or an inert gas element, such as He, Ne, or the like, is ion implanted via the interlayer insulating film **45** to the P-well region of the semiconductor substrate. Thus, the release layer including the release material is formed in the semiconductor substrate.

Next, a SiO₂ film is formed to cover the semiconductor substrate and the interlayer insulating film **45**, and is then planarized by chemical mechanical polishing (CMP) or the like, to form the interlayer insulating layer **44**.

Next, the source electrode **51s** and the drain electrode **51d** are formed. Initially, the contact holes **54s** and **54d** penetrating the interlayer insulating film **44**, the interlayer insulating film **45**, the insulating film **46**, and the gate oxide film **47** are formed. The contact hole **54s** is formed above the source region **53s**, while the contact hole **54d** is formed above the drain region **53d**. Thereafter, a conductive material is provided in the contact holes **54s** and **54d** and on a surface of the interlayer insulating film **44**, and is then patterned. As a result, the source electrode **51s** is formed above the contact hole **54s**, while the drain electrode **51d** is formed above the contact hole **54d**. Next, the insulating film **43** is formed, and a surface thereof is then planarized by CMP or the like.

Next, the surface of the insulating film **43** is washed, and thereafter, the planarized surface is bonded to the glass substrate **22** in accordance with the alignment mark **41**, and a thermal treatment is performed at a temperature of about 400-600° C. As a result, a portion of the semiconductor substrate including the P-well region is separated along the release layer, and thereafter, the MOS transistor **42** of the peripheral device unit **40** is transferred onto the glass substrate **22**. Note that, in this embodiment, the semiconductor substrate a portion of which is separated in the separation step is referred to as the semiconductor layer **52**.

Thus, as shown in FIG. 2, the peripheral device unit **40** is formed on the glass substrate **22** before the thin film device unit **20** is formed.

Next, as shown in FIG. 3, the base coat layers **24** and **25** are formed on a display region of the glass substrate **22** and on the peripheral device unit **40** in a peripheral region of the glass substrate **22**.

Next, the TFT **21** is formed in the display region of the base coat layer **25**. Specifically, the semiconductor layer **23** is patterned on a surface of the base coat layer **25** by photolithography. In this case, if an alignment mark for formation of a thin film device is previously formed in the display region of the glass substrate **22**, the TFT **21** can be formed with high accuracy.

Next, the gate insulating film **26** is stacked on the base coat layer **25** to cover the semiconductor layer **23**.

Next, a mask is formed on a portion of the semiconductor layer **23** corresponding to a position where the channel region **23c** is to be formed, and an impurity element is ion implanted, to form the channel region **23c** and the low-concentration impurity regions on the opposite sides of the channel region **23c**, in the semiconductor layer **23**.

Next, the mask is removed. Thereafter, as shown in FIG. 4, the gate electrode **27** is formed by patterning using photolithography so that the gate electrode **27** overlaps the channel region **23c** of the semiconductor layer **23** and a portion of the opposite sides of the channel region **23c**. By ion implanting an impurity element into the semiconductor layer **23** using the gate electrode **27** as a mask, the LDD regions **23s'** and **23d'** and the source and drain regions **23s** and **23d** are formed so that the channel region **23c** is interposed therebetween.

Next, as shown in FIG. 5, the gate insulating film **26** and the gate electrode **27** are covered with the protective film **28**.

Next, as shown in FIG. 6, the base coat layers **24** and **25**, the gate insulating film **26**, and the protective film **28** on a boundary portion between the display region and the peripheral device unit **40**, and on the peripheral device unit **40** are removed by etching. Moreover, by etching the semiconductor layer **52**, surfaces of the LOCOS oxide film **48** and the active region **53** are exposed.

Next, as shown in FIG. 7, the TEOS film **55**, the SiN film **56**, and the TEOS film **57** as insulating films are formed which extend over the protective film **28** in the display region and the peripheral device unit **40**.

Next, as shown in FIG. 8, the contact holes **58s**, **58d**, and **59s** are formed. The contact holes **58s** and **58d** penetrate the TEOS film **55**, the SiN film **56**, the TEOS film **57**, the protective film **28**, and the gate insulating film **26** to reach the source region **23s** and the drain region **23d** of the semiconductor layer **23**, respectively. The contact hole **59s** penetrates the TEOS film **55**, the SiN film **56**, the TEOS film **57**, the LOCOS oxide film **48**, the interlayer insulating film **44**, the interlayer insulating film **45**, and the insulating film **46** to reach the source electrode **51s** of the peripheral device unit **40**.

Next, as shown in FIG. 9, the contact holes **58d**, **58s**, and **59s** are filled with a conductive material to form the interconnection portions **60d**, **60s**, and **61s**, respectively. Next, the passivation film **62**, and the resin film **63** as a planarizing film are formed to cover the TFT **21** and the interconnection portions **60d**, **60s**, and **61s** of the peripheral device unit **40**.

A portion where the resin film **63** is not formed is provided on each of the interconnection portions **60s** and **61s**, and the conductive film **64** made of ITO or the like is formed which extends over the portions and a part of the resin film **63**. Thus, the element substrate **11** is completely produced.

Advantages of First Embodiment

According to the first embodiment, because the peripheral device unit **40** is bonded directly to the glass substrate **22**, there is not a film or the like interposed between the flat glass substrate **22** and the peripheral device unit **40**. Therefore, the glass substrate **22** and the peripheral device unit **40** are satisfactorily attached to each other. Moreover, because a sacrificial film or the like is not formed on the glass substrate **22**, the manufacturing efficiency of the device is satisfactorily high. Moreover, because the peripheral device unit **40** is bonded to the glass substrate **22** before the thin film device unit **20** is formed, there is not residue of a sacrificial film or the like on the glass substrate **22** before the peripheral device unit **40** is bonded to the glass substrate **22**, and therefore, warpage due to a thermal treatment or the like does not occur. Therefore, the peripheral device unit **40** can be bonded to a flatter surface of the glass substrate **22**. As a result, the glass substrate **22** and the peripheral device unit **40** are more satisfactorily attached to each other.

Moreover, because the alignment mark **41** for formation of the peripheral device unit **40** is provided on the glass substrate **22** before the peripheral device unit **40** is bonded to the glass substrate **22**, the peripheral device unit **40** can be bonded to the glass substrate **22** with high accuracy and efficiency.

Moreover, because the thin film device unit **20** includes the TFTs **21** including an amorphous silicon semiconductor layer or a polycrystalline silicon semiconductor layer, the thin film device unit **20** has good qualities, such as a faster response time of the TFT **21** and the like.

Moreover, because the peripheral device unit **40** includes the semiconductor layer **52** made of monocrystalline silicon, the peripheral device unit **40** has good qualities, such as a higher carrier mobility of the semiconductor layer **52** and the like.

Second Embodiment

Next, a second embodiment of the present invention will be described. The second embodiment has a feature that a planarizing film is provided at a step portion between a thin film device unit and a peripheral device unit.

FIGS. 11-17 are cross-sectional views for describing an element substrate 111 which is a semiconductor device, in the order in which the element substrate 111 is manufactured.

Method for Manufacturing Device Substrate 111

Initially, as shown in FIG. 11, a glass substrate 122 is prepared, and an alignment mark 141 for positioning during formation of a peripheral device unit is formed on a surface of the glass substrate 122.

Moreover, in a separate step, a peripheral device unit 140 which is to be bonded to the glass substrate 122 is produced. The peripheral device unit 140 is produced and configured in a manner similar to that of the peripheral device unit 40 of the first embodiment. Therefore, in FIGS. 12-17, reference characters for the components of the peripheral device unit 140 are not shown.

The peripheral device unit 140 is formed in a manner similar to that of the first embodiment, and is bonded to the glass substrate 22 in accordance with the alignment mark 141. Thereafter, the resultant structure is subjected to a thermal treatment at a temperature of about 400-600° C. to separate a portion of the semiconductor substrate including a P-well region along a release layer.

Thus, as shown in FIG. 12, the peripheral device unit 140 is formed on the glass substrate 122 before a thin film device unit 120 is formed.

Next, as shown in FIG. 13, base coat layers 124 and 125 are formed on a display region of the glass substrate 122 and on the peripheral device unit 140 in a peripheral region of the glass substrate 122. Moreover, a semiconductor layer 123 is formed on the base coat layer 125. The semiconductor layer 123 includes a channel region 123c, LDD regions 123s' and 123d' formed on opposite sides of the channel region, and a source region 123s and a drain region 123d between which the channel region 123c and the LDD regions 123s' and 123d' are interposed. Next, a gate insulating film 126 is formed on the base coat layer 125 and the semiconductor layer. Moreover, a gate electrode 127 is formed in a display region of the gate insulating film 126 by patterning using photolithography.

Next, as shown in FIG. 14, the gate insulating film 126 and the gate electrode 127 are covered with a protective film 128. Next, the base coat layers 124 and 125, the gate insulating film 126, and the protective film 128 on a boundary portion between the display region and the peripheral device unit 140, and on the peripheral device unit 140 are removed by etching. Moreover, the semiconductor layer of the peripheral device unit 140 is etched to expose surfaces of the LOCOS oxide film and the active region. Next, a TEOS film 155, a SiN film 156, and a TEOS film 157 as insulating films are formed which extend over the protective film 128 in the display region and the peripheral device unit 140.

Next, as shown in FIG. 15, a planarizing film 161 made of a resin material is formed which extends over the thin film device unit 120, a step portion 160 between the thin film device unit 120 and the peripheral device unit 140, and the peripheral device unit 140.

Next, as shown in FIG. 16, all the planarizing film 161 is removed by etching, except for a region thereof corresponding the step portion 160. As a result, the step portion 160 between the thin film device unit 120 and the peripheral device unit 140 is filled and planarized with the planarizing film 161.

Next, as shown in FIG. 17, an insulating film 162 is formed which extends over the thin film device unit 120, the planarizing film 161, and the peripheral device unit 140. Next, contact holes 158s, 158d, and 159s are formed. The contact holes 158s and 158d penetrate the TEOS film 157, the SiN film 156,

the TEOS film 155, the protective film 128, and the gate insulating film 126 to reach the source region 123s and the drain region 123d of the semiconductor layer 123, respectively. The contact hole 159s penetrates the TEOS film, the SiN film, the TEOS film, the LOCOS oxide film, the inter-layer insulating film, and the insulating film to reach the source electrode of the peripheral device unit 140. Next, a conductive material is provided in the contact holes 158s, 158d, and 159s, and on the insulating film 162 before a predetermined etching treatment is performed. As a result, a metal interconnection 163 for electrically connecting the thin film device unit 120 and the peripheral device unit 140 is formed. Moreover, various steps are performed to produce the element substrate 111 including a plurality of TFTs which are provided in a matrix on the substrate.

Advantages of Second Embodiment

According to the second embodiment, the element substrate 111 has advantages similar to those of the first embodiment. Moreover, because the planarizing film 161 is formed on the step portion 160, it is possible to satisfactorily reduce or prevent damage to an interconnection, a layer, and the like which extend over the thin film device unit 120 and the peripheral device unit 140.

Moreover, in the second embodiment, the metal interconnection 163 for electrically connecting the thin film device unit 120 and the peripheral device unit 140 is formed on the planarizing film 161. Therefore, the metal interconnection 163 is not affected by the step portion 160. As a result, the occurrence of a disconnection or the like of the metal interconnection 163 due to bending or the like can be satisfactorily reduced or prevented.

Moreover, because the planarizing film 161 is formed of a resin material, the planarizing film 161 which flexibly fits the shape of the step portion 160 can be formed, resulting in a more satisfactory flatness of the step portion 160.

While, in the first and second embodiments, the glass substrates 22 and 122 are used as substrates, the present invention is not limited to this, and any substrate that has an insulating surface may be employed. For example, a plastic substrate, a quartz substrate, or the like may be employed.

Moreover, the peripheral device units 40 and 140 of the first and second embodiments may be any one that can be provided around the thin film device units 20 and 120 and has a semiconductor element. Examples of such a peripheral device unit include high-performance devices and the like required for system integration, such as drivers, and memories, microprocessors, image processors, timing controllers, and the like for which higher performance is required.

Moreover, while, in the second embodiment, the planarizing film 161 is formed of a resin material, the present invention is not limited to this. For example, the planarizing film 161 may be formed of a spin-on-glass (SOG) material or the like. Here, the SOG material is one that is used as an insulating film or a planarization material in some processes. The SOG material is a solution which is obtained by dissolving a silicate compound in an organic solvent. By using the SOG material, a film including silicate glass (SiO₂) as a major component can be formed.

INDUSTRIAL APPLICABILITY

As described above, the present invention is useful for semiconductor device manufacturing methods and semiconductor devices.

The invention claimed is:

1. A semiconductor device comprising:
 - a substrate having an insulating surface;

11

a thin film device unit provided on the substrate;
a peripheral device unit provided on the substrate around
the thin film device unit, and including a semiconductor
element;
a step portion formed between the thin film device unit and 5
the peripheral device unit;
a planarizing film formed only in a region corresponding to
the step portion;
a metal interconnection formed on the planarizing film, for
electrically connecting the thin film device unit and the 10
peripheral device unit, wherein

12

the peripheral device unit is provided directly on the insu-
lating surface of the substrate.
2. The semiconductor device of claim 1, wherein
the planarizing film is formed of a resin or SOG.
3. The semiconductor device of claim 1, wherein
the substrate having the insulating surface is made of glass,
plastic, or quartz.
