**Description****FIELD**

[0001] The present disclosure relates generally to vehicle diagnostics, and more particularly to devices and methods for determining a vehicle alternator condition.

**BACKGROUND**

[0002] Most vehicles nowadays are powered by internal combustion engines in which a fuel mixture is ignited thus generating mechanical power, which is in turn converted to rotational motion of the vehicle's wheels. Motor vehicles need electricity to operate. For example, electric energy is needed to power lights, gauges, an air conditioning system, an entertainment system, and other electrically powered components ("electrical components") of the vehicle. For gasoline engines, electric energy is also needed to power the spark plugs which ignite the fuel mixture. Accordingly, vehicles are equipped with batteries for providing electric energy to power the electrical components. A vehicle battery will lose its charge if it is the sole source of electric energy in the vehicle. Accordingly, vehicles are equipped with electric generators, which convert the mechanical energy produced by the internal combustion engine to electric energy and use that electric energy to charge the vehicle battery. An example of an approach for predicting an alternator failure in a motor vehicle is presented in document US2019385386 A1.

**SUMMARY**

[0003] In one aspect of the present disclosure, there is provided a method by a telematics device for predicting an alternator failure in a motor vehicle. The method comprises entering into a sleep mode then performing a plurality of micro wakeups during the sleep mode, capturing a first plurality of voltage values corresponding to the plurality of micro wakeups, and waking up from the sleep mode and checking for an ignition signal. If the ignition signal is detected, the method further comprises determining a maximum cranking voltage and a maximum cranking voltage timestamp from the first plurality of voltage values, capturing a second plurality of voltage values, determining a maximum device voltage and a maximum device voltage timestamp from the second plurality of voltage values, and determining a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold.

[0004] Performing the plurality of micro wakeups may comprise powering up a limited number of peripherals of the telematics device.

[0005] Capturing the first plurality of voltage values may comprise measuring a voltage at a battery terminal

of the motor vehicle in each micro wakeup of the plurality of micro wakeups.

[0006] Waking up from the sleep mode may comprise powering up most peripherals of the telematics device.

[0007] Checking for the ignition signal may comprise checking for one or more messages received over an interface port of the motor vehicle indicating that ignition is turned on in the motor vehicle

[0008] Determining the maximum cranking voltage and the maximum cranking voltage timestamp from the first plurality of voltage values may comprise determining a maximum voltage value of the first plurality of voltage values and determining a corresponding maximum voltage value timestamp.

[0009] Capturing the second plurality of voltage values may comprise measuring a voltage at a battery terminal of the motor vehicle subsequent to receiving the ignition signal.

[0010] Determining the maximum device voltage and the maximum device voltage timestamp from the second plurality of voltage values may comprise determining a maximum voltage value of the second plurality of voltage values and determining a corresponding maximum voltage value timestamp.

[0011] In another aspect of the present disclosure, there is provided a telematics device coupled to a motor vehicle, the telematics device comprising a controller, an asset interface coupled to the controller, and a memory storing machine-executable instructions. The machine-executable instructions when executed by the controller, configure the telematics device to enter into a sleep mode then perform a plurality of micro wakeups during the sleep mode, capture a first plurality of voltage values corresponding to the plurality of micro wakeups, and wake up from the sleep mode and check for an ignition signal. If the ignition signal is detected the machine-executable instructions further configure the telematics device to determine a maximum cranking voltage and a maximum cranking voltage timestamp from the first plurality of voltage values, capture a second plurality of voltage values, determine a maximum device voltage and a maximum device voltage timestamp from the second plurality of voltage values, and determine a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold.

[0012] The machine-executable instructions which configure the telematics device to perform the plurality of micro wakeups may comprise machine-executable instructions which power up a limited number of peripherals of the telematics device.

[0013] The machine-executable instructions which configure the telematics device to capture the first plurality of voltage values may comprise machine-executable instructions which configure the telematics device to measure a voltage at a battery terminal of the motor vehicle in each micro wakeup of the plurality of micro wake-

ups.

**[0014]** The machine-executable instructions which configure the telematics device to wake up from the sleep mode may comprise machine-executable instructions which configure the telematics device to power up most peripherals of the telematics device.

**[0015]** The machine-executable instructions which configure the telematics device to check for an ignition signal, may comprise machine-executable instructions which configure the telematics device to examine one or more messages received over an interface port of the motor vehicle indicating that ignition is turned on in the motor vehicle

**[0016]** The machine-executable instructions which configure the telematics device to determine the maximum cranking voltage and the maximum cranking voltage timestamp from the first plurality of voltage values may comprise machine-executable instructions which configure the telematics device to determine a maximum voltage value of the first plurality of voltage values and determine a corresponding timestamp of the maximum voltage value.

**[0017]** The machine-executable instructions which configure the telematics device to capture the second plurality of voltage values may comprise machine-executable instructions which configure the telematics device to measure a voltage at a battery terminal of the motor vehicle subsequent to receiving the ignition signal.

**[0018]** The machine-executable instructions which configure the telematics device to capture the second plurality of voltage values may comprise machine-executable instructions which configure the telematics device to capture the second plurality of voltage values for a predetermined duration after detecting the ignition signal.

**[0019]** The machine-executable instructions which configure the telematics device to determine the maximum device voltage and the maximum device voltage timestamp from the second plurality of voltage values comprise machine-executable instructions which configure the telematics device to determine a maximum voltage value of the second plurality of voltage values and determine a corresponding timestamp of the maximum voltage value.

**[0020]** In any of the preceding aspects, the undercharging indicator duration threshold may be 200 seconds.

**[0021]** A system of one or more computers can be configured to perform particular operations or actions by virtue of having software, firmware, hardware, or a combination of them installed on the system that in operation causes or cause the system to perform the actions. One or more computer programs can be configured to perform particular operations or actions by virtue of including instructions that, when executed by data processing apparatus, cause the apparatus to perform the actions. One general aspect includes a method by a telematics device. The method includes receiving a maximum cranking volt-

age and a maximum cranking voltage timestamp from the motor vehicle over an asset interface of the telematics device; receiving a maximum device voltage and a maximum device voltage timestamp from the motor vehicle over the asset interface, and determining a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold. Other embodiments of this aspect include corresponding computer systems, apparatus, and computer programs recorded on one or more computer storage devices, each configured to perform the actions of the methods.

**[0022]** Implementations may include one or more of the following features. The method where the undercharging indicator duration threshold is 200 seconds. The method may include repeating the steps of receiving and determining a plurality of times and activating an alerting device in response to the determining of the potential alternator undercharging condition more than once in the plurality of times. Activating the alerting device may include activating an indicator light. Activating the alerting device may include activating a buzzer. Implementations of the described techniques may include hardware, a method or process, or computer software on a computer-accessible medium.

**[0023]** One general aspect includes a telematics device. The telematics device also includes a controller; an asset interface coupled to the controller; and a non-transitory memory storing machine-executable instructions which, when executed by the controller, configure the telematics device to: receive a maximum cranking voltage and a maximum cranking voltage timestamp from a motor vehicle over the asset interface; receive a maximum device voltage and a maximum device voltage timestamp from the motor vehicle over the asset interface; and determine a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold. The undercharging indicator duration threshold may be 200 seconds. The machine-executable instructions may further comprise machine-executable instructions which repeat the steps of receiving the maximum cranking voltage and maximum cranking voltage timestamp, receiving the maximum device voltage and maximum device voltage timestamp and determining the potential alternator undercharging condition a plurality of times and activate an alerting device in response to determining of the potential alternator undercharging condition more than once in the plurality of times.

**[0024]** The machine-executable instructions which activate the alerting device may comprise machine-executable instructions which activate an indicator light.

**[0025]** The machine-executable instructions which activate the alerting device may comprise machine-executable instructions which activate a buzzer.

**[0026]** Other embodiments of this aspect include cor-

responding computer systems, apparatus, and computer programs recorded on one or more computer storage devices, each configured to perform the actions of the methods.

**[0027]** One general aspect includes a method. The method includes receiving, by a telematics device, a maximum cranking voltage and a maximum cranking voltage timestamp from a motor vehicle over an asset interface of the telematics device; receiving, by the telematics device, a maximum device voltage and a maximum device voltage timestamp from the motor vehicle over the asset interface of the telematics device; sending, by the telematics device, the maximum cranking voltage, the maximum cranking voltage timestamp, the maximum device voltage, and the maximum device voltage timestamp, over a network interface, to a telematics server; and determining a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold.

**[0028]** The method may further comprise sending, by the telematics server, an indication of a potential alternator undercharging condition to an administration terminal over the network interface.

**[0029]** The undercharging indicator duration threshold may be 200 seconds.

**[0030]** One general aspect includes a method by a telematics device. The method also includes receiving a maximum cranking voltage and a maximum cranking voltage timestamp from the motor vehicle over an asset interface of the telematics device; receiving a maximum device voltage and a maximum device voltage timestamp from the motor vehicle over the asset interface; and sending the maximum cranking voltage, the maximum cranking voltage timestamp, the maximum device voltage, and the maximum device voltage timestamp, over a network interface, to a telematics server. Other embodiments of this aspect include corresponding computer systems, apparatus, and computer programs recorded on one or more computer storage devices, each configured to perform the actions of the methods.

**[0031]** Implementations may include one or more of the following features. The method may include repeating the steps of receiving and sending. The method may include receiving an indication, from the telematics server, of an alternator undercharging condition. The method may include activating an alerting device in response to receiving the indication of an alternator undercharging condition. Activating an alerting device may include activating an indicator light. Activating an alerting device may include activating a buzzer. Implementations of the described techniques may include hardware, a method or process, or computer software on a computer-accessible medium.

**[0032]** One general aspect includes a telematics device. The telematics device also includes a controller; an asset interface coupled to the controller; a network inter-

face coupled to the controller; and a non-transitory memory storing machine-executable instructions which, when executed by the controller, configure the telematics device to: receive a maximum cranking voltage and a maximum cranking voltage timestamp from a motor vehicle over the asset interface; receive a maximum device voltage and a maximum device voltage timestamp from the motor vehicle over the asset interface; and send the maximum cranking voltage, the maximum cranking voltage timestamp, the maximum device voltage, and the maximum device voltage timestamp, over the network interface, to a telematics server. Other embodiments of this aspect include corresponding computer systems, apparatus, and computer programs recorded on one or more computer storage devices, each configured to perform the actions of the methods.

**[0033]** One general aspect includes a method by a telematics server. The method also includes receiving, over a network interface, from a telematics device a maximum cranking voltage, a maximum cranking voltage timestamp, a maximum device voltage, and a maximum device voltage timestamp associated with a motor vehicle coupled to the telematics device; and determining a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold. Other embodiments of this aspect include corresponding computer systems, apparatus, and computer programs recorded on one or more computer storage devices, each configured to perform the actions of the methods.

**[0034]** Implementations may include one or more of the following features. The method may include sending an indication of a potential alternator undercharging condition to an administration terminal over the network interface. Implementations of the described techniques may include hardware, a method or process, or computer software on a computer-accessible medium.

**[0035]** One general aspect includes a telematics server. The telematics server also includes a controller; a network interface coupled to the controller; and a non-transitory memory storing machine-executable instructions which, when executed by the controller, configure the telematics server to: receive, over the network interface, from a telematics device a maximum cranking voltage, a maximum cranking voltage timestamp, a maximum device voltage, and a maximum device voltage timestamp associated with a motor vehicle coupled to the telematics device; determine, by an analysis module, a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold. Other embodiments of this aspect include corresponding computer systems, apparatus, and computer programs recorded on one or more computer storage devices, each configured to perform the actions of the methods.

**[0036]** Implementations may include one or more of

the following features. The telematics server where the machine-executable instructions when executed by the controller, further configure the telematics server to send, by an alert module, an indication of a potential alternator undercharging condition to an administration terminal over the network interface. Implementations of the described techniques may include hardware, a method or process, or computer software on a computer-accessible medium.

## BRIEF DESCRIPTION OF THE DRAWINGS

### [0037]

Figure 1 is a simplified diagram depicting an internal combustion engine mechanically coupled to both an alternator and a starter motor.

Figure 2 is a block diagram showing the logical components of an alternator.

Figure 3A is a schematic diagram showing selected components of an automotive electric system and current flow therebetween when the vehicle engine is off.

Figure 3B is a schematic diagram of the components of Figure 3B and current flow during a cranking event.

Figure 3C is a schematic diagram of the automotive electric system of Figure 3C during normal engine operation.

Figure 4 is a graph depicting cranking and device voltages in an automotive electric system during and subsequent to a cranking event.

Figure 5 is a vehicle charging profile depicting cranking and device voltages in an automotive electric system in which the alternator is undercharging the battery.

Figure 6 is a graph depicting cranking and device voltages in an automotive electric system in which the alternator is overcharging the battery.

Figure 7A is a histogram of the distribution of the duration between the maximum cranking voltage and the maximum device voltage for an international motor vehicle.

Figure 7B is a histogram of the distribution of the duration between the maximum cranking voltage and the maximum device voltage for a Chevrolet Equinox.

Figure 7C is a histogram of the distribution of the duration between the maximum cranking voltage

and the maximum device voltage for a Chevrolet Silverado.

Figure 7D is a histogram of the distribution of the duration between the maximum cranking voltage and the maximum device voltage for a Dodge Ram.

Figure 8 is a histogram showing the distribution of normal, overcharging, and undercharging events in a Ford Transit vehicle.

Figure 22 is a graph showing a power-saving scheme implementing a plurality of regular wakeups with a plurality of micro wakeups interleaved therebetween, and a cranking and device voltage curve superimposed thereon.

## DETAILED DESCRIPTION

**[0038]** In this disclosure, the terms "electricity," "electric energy," "electrical energy" and "electrical power" are used interchangeably and refers to electrical energy. A skilled person would understand that electricity is a form of energy, and that power is energy in a unit time. An electric battery or a generator provide electricity, electric energy, or electric power to power one or more electrical components.

**[0039]** In this disclosure, the terms "generator" and "alternator" are used interchangeably and refers to an alternating current (AC) generator deployed in conjunction with an engine for converting rotational mechanical energy to electrical energy.

**[0040]** In this disclosure, the terms "electric battery," "vehicle battery," or "battery" refer to a battery deployed in a vehicle to provide electric energy to one or more electrical components. A vehicle battery may be a lead acid battery or any other suitable type of battery.

### Vehicles and Batteries

**[0041]** Motor vehicles are equipped with batteries for providing electric energy to power the electrical components thereof. Typical vehicle batteries are either 12V batteries or 24V batteries. In this disclosure, mainly 12V batteries will be discussed, but it would be apparent to those of skill in the art that the methods described would be equally applicable to 24V batteries, and to batteries operating at other voltages. A vehicle battery needs to be charged such that it provides a battery output voltage which is in a battery operating voltage range. The battery operating voltage range has a lower battery output voltage limit and an upper battery output voltage limit. When the vehicle battery output voltage drops below the lower battery output voltage limit, the battery is considered undercharged and needs to be charged or it will not provide sufficient electrical power to the various electrical components. In the example of a 12V battery, the lower battery output voltage limit has been found to be 12.2V. When the vehicle battery output voltage rises above the

upper battery output voltage limit, the vehicle battery is considered overcharged. An overcharged battery may deteriorate quickly and the vehicle battery output voltage, which is higher than the upper battery output voltage limit, may cause damage to some of the electrical components of the vehicle. In the example of a 12V battery, the upper battery output voltage limit has been found to be 12.6V. It is therefore generally desirable to keep the battery output voltage of a 12V vehicle battery between 12.2V and 12.6V.

### Cranking

**[0042]** Internal combustion engines need to be cranked to start their operation. Cranking an engine involves rotating the engine's crank shaft causing the pistons to move in a reciprocating manner within their corresponding cylinders. Rotating the crank shaft also causes intake valves to open letting air into the cylinders and causes an injection pump to inject fuel into the cylinders. For engines using carburetors, the intake valves let a fuel mixture of gasoline and air into the cylinders. For gasoline engines, cranking also causes the spark plugs to be activated thus igniting the fuel mixture and producing heat energy which displaces the pistons inside the cylinders. The displacement of the pistons in a reciprocating manner within the cylinders is converted to rotary motion by the crank shaft, and the engine is said to have been started. Cranking an engine is typically done by a starter motor mechanically coupled to the engine. The starter motor relies mainly on the vehicle battery to run during cranking.

### Alternator

**[0043]** Electricity generators used in vehicles are often referred to as alternators since they generate electricity having an alternating current (AC). The generated AC is then rectified and converted to direct current (DC) to power the vehicle's electrical components and to charge the vehicle's battery. An alternator is mechanically coupled to a vehicle's internal combustion engine and converts mechanical energy provided by the engine to electrical energy. In order to charge a vehicle battery to a particular output voltage, an alternator is configured to generally produce an alternator output voltage which is higher than the battery voltage by a charging voltage offset. Accordingly, an alternator has a lower alternator output voltage limit, which is greater than a corresponding lower battery output voltage limit by the charging voltage offset. Similarly, an alternator has an upper alternator output voltage limit which is greater than a corresponding upper battery output voltage limit by the charging voltage offset. By way of example, a charging voltage offset may be 1V. For a 12V battery, the lower battery output voltage limit is 12.2V and accordingly the lower alternator output voltage limit is 13.2V for an alternator configured to charge the battery by a charging voltage offset of 1V. Similarly, for the 12V battery, the upper battery output voltage limit is 12.6V

and accordingly the upper alternator output voltage limit is 13.6V for an alternator configured to charge the battery by a charging offset of 1V.

### Alternator Failure

**[0044]** Alternators often fail after a period of use. In some cases, the alternator completely fails and does not produce any electric energy at all. In other cases, the alternator is either overcharging or undercharging the vehicle battery. If the alternator output voltage is less than the lower alternator output voltage limit, then the alternator is said to be "undercharging" the vehicle battery. For example, for a 12V vehicle battery discussed above and a charging offset voltage of 1V, if the alternator output voltage is less than the lower alternator output voltage limit of 13.2V, the alternator is said to be undercharging the vehicle battery. If the alternator output voltage is greater than the upper alternator output voltage limit of 13.6, the alternator is said to be "overcharging" the vehicle battery.

**[0045]** An alternator is mechanically and rotationally coupled a vehicle's engine in order to produce electricity. Similarly, a starter motor is mechanically and rotationally coupled to a vehicle's engine in order to crank the engine. With reference to Figure 1, there is shown an engine 20 mechanically coupled to both an alternator 30 and a starter motor 70.

**[0046]** The engine 20 comprises a plurality of cylinders (now shown) in which a corresponding plurality of pistons are disposed and configured for reciprocating motion. The engine 20 also houses a crankshaft (not shown) mechanically coupled to the pistons. As known in the art, the reciprocating motion of the pistons are converted to rotational motion by the crankshaft. At one end of the crankshaft, there is a drive pulley 24 connected with the crankshaft and rotatable therewith. At the opposite end of the crankshaft, there is a flywheel 28 connected with the crankshaft and rotatable therewith. The flywheel 28 may be in the form of a gear and have a plurality of teeth.

**[0047]** An alternator 30 is disposed alongside the engine 20 and rotationally coupled thereto. The alternator 30 may be affixed to the engine block or to any part of the vehicle chassis. The alternator 30 includes an alternator pulley 40 connected to and rotatable with an alternator shaft. The alternator pulley 40 is rotationally coupled to the drive pulley 24, typically by an alternator belt 42. Accordingly, the alternator shaft rotates with the rotation of the engine crankshaft.

**[0048]** A starter motor 70 is disposed alongside the engine 20. The starter motor 70 has a starter motor shaft 74 which provides rotational motion when electric power is provided to the starter motor 70. A starter motor pinion gear 76 is connected to the starter motor shaft 74 and is rotatable therewith. A starter motor solenoid 72 allows extending and retracting the starter motor shaft 74. To start the engine 20, the starter motor solenoid 72 extends the starter motor shaft 74 until the starter motor pinion

gear 76 engages with the flywheel 28 and rotates the engine's crankshaft. Once the engine has started, the starter motor solenoid 72 retracts the starter motor shaft 74 so that the starter motor pinion gear 76 disengages from the flywheel 28.

**[0049]** When the engine 20 is off and is not being cranked (started), the crank shaft is not rotating and accordingly the drive pulley 24 is not rotating. As a result, the alternator pulley 40 is also not rotating and no electric power is generated by the alternator 30. Similarly, no power is applied to the starter motor 70 and hence the starter motor pinion gear 76 does not rotate. Additionally, the starter motor shaft 74 is in retracted mode towards the starter motor 70 and the starter motor pinion gear 76 is not engaged with the flywheel 28.

**[0050]** When the engine 20 is cranked (started), for example by a user turning a key in an ignition or actuating a push button ignition switch, electric power is applied from the vehicle's battery to the starter motor 70 including the starter motor solenoid 72. In response to receiving electric power, the solenoid extends the starter motor shaft 74 until the teeth of the starter motor pinion gear 76 engage with the teeth of the flywheel 28, as shown in dotted lines in the figure. Additionally, the starter motor 70 rotates the starter motor shaft 74 thus rotating the starter motor pinion gear 76 therewith. Since the flywheel 28 is in engagement with the starter motor pinion gear 76, the flywheel 28 rotates in the opposite direction to that of the starter motor pinion gear 76. The crankshaft rotates with the flywheel 28. As discussed above, the rotation of the crankshaft causes the engine to start. The drive pulley 24 rotates with the crankshaft. Since the alternator pulley 40 is rotationally coupled to the drive pulley 24 by the alternator belt 42, the alternator pulley 40 also rotates and the alternator 30 generates some electricity.

**[0051]** When the engine 20 is running, the starter motor 70 is turned off. Additionally, the starter motor solenoid 72 retracts the starter motor shaft 74 such that the starter motor pinion gear 76 is disengaged from the flywheel 28. As the engine is running, the drive pulley 24 is rotating by the action of the mechanical rotational motion produced by the engine 20. The alternator 30 rotates with the engine 20 and produces electricity to power the electrical components of the vehicle.

**[0052]** The structure and operation of an alternator 30 are known in the art. For illustration, Figure 2 shows a high-level block diagram of an alternator 30 identifying its principal components. An alternator 30 includes a rotor 32, a stator 34, an alternator housing 44, a rectifier 36, and a regulator 38.

**[0053]** The rotor 32 is disposed on a shaft and rotatable therewith. The rotor 32 features an electromagnet (not shown) which is powered by the vehicle's battery and/or electric power generated by the alternator 30 itself. The power of the electromagnet affects the alternator output voltage. The higher the power of the electromagnet, the higher the alternator output voltage for the same rota-

tional speed of the rotor shaft. Conversely, the lower the power of the electromagnet, the lower the alternator output voltage for the same rotational speed of the rotor shaft.

**[0054]** The stator 34 is circumferentially disposed inside the alternator housing 44 encompassing the rotor 32. The stator 34 consists of a plurality of coils typically connected in a star configuration, as known in the art. The coils have terminals at which the generated AC is provided.

**[0055]** The rectifier 36 converts the generated AC provided at the terminals of the coils into DC. In some example embodiments, the rectifier comprises a plurality of diodes, and at least one capacitor as known in the art. For a typical 3-phase alternator, there are at least 3 diodes.

**[0056]** The regulator 38 detects the alternator output voltage and ensures that it remains above the lower alternator output voltage limit and below the upper alternator output voltage limit. As shown the regulator 38 checks the battery output voltage and the alternator output voltage. As discussed above, the alternator output voltage is generally higher than the battery output voltage by a charging voltage offset. The regulator 38 determines the desired alternator output voltage based on the battery output voltage. If the alternator output voltage is different from the desired alternator output voltage, the regulator controls the power provided to the electromagnet of the rotor in order to maintain the alternator output voltage between the lower alternator output voltage limit and the upper alternator output voltage limit.

**[0057]** Rotating the alternator pulley 40 causes the rotor 32 to rotate with respect to the stator 34 and induce electricity in the stator 34. The generated electricity is in the form of an alternating current (AC) which is provided at the stator terminals (not shown). The rectifier 36 converts the generated AC to direct current (DC) output. The DC output may be provided to charge the vehicle battery, power the electromagnet of the rotor 32, and power the electrical components of the vehicle while the engine 20 is running.

**[0058]** The regulator 38 determines the desired alternator output voltage based on the battery operating voltage range. The regulator 38 then compares the alternator output voltage, provided thereto by the rectifier, as shown, with the desired alternator output voltage. Based on the comparison, the regulator may increase or decrease the electric power provided to the electromagnet of the rotor 32. For example, for a 12V battery, the alternator output voltage needs to be between 13.2V and 13.6V. If the alternator output voltage was at 14V, then the alternator is overcharging the battery. The regulator 38 reduces the power provided to the electromagnet of the rotor 32. As a result, the alternator output voltage is reduced. This is repeated until the alternator output voltage is at most at the upper alternator output voltage limit of 13.6V. Conversely, if the alternator output voltage is below 13.2V, the regulator 38 increases the electric power

provided to the rotor 32. As a result, the alternator output voltage is increased (for the same alternator shaft rotational speed), thus increasing the alternator output voltage. This is repeated until the alternator output voltage is at least at the lower alternator output voltage limit.

**[0059]** The electrical connections between the engine 20, the starter motor 70 and the alternator 30 are shown in Figures 3A-3C.

**[0060]** Figures 3A-3C depict a simplified schematic of a vehicle's electric subsystems including a battery 60, a starter motor 70, an alternator 30, a voltage-sensing device 106, and an electrical component 80 shown as a light bulb. The battery 60 may be a lead acid battery or any other suitable type of battery used in vehicles. The battery 60 has a positive battery terminal 62 connected to the electrical component 80, to the starter motor 70 and to the alternator 30. The battery 60 also has a negative terminal 64 connected to the ground (i.e., the vehicle's metal chassis). The starter motor 70 is connected to the positive battery terminal 62 and to the ground. The alternator is connected to the positive battery terminal 62 and to the ground. The electrical component 80 may be any one of vehicle lights, gauges, air conditioner or entertainment system. The voltage-sensing device 106 is connected to the positive battery terminal 62 and the alternator output. The voltage measuring device may be a voltmeter, galvanometer, analog-to-digital converter (ADC), or any other suitable device that can measure voltage.

**[0061]** Turning first to Figure 3A. In this figure, the engine 20 is in off mode. In other words, the engine 20 is neither running nor being cranked. Accordingly, the alternator 30 is not rotating and is not producing any electric power. The only source of electricity in the vehicle is the battery 60. Thickened black lines in Figure 3A show current flow between the battery 60 and the electrical component 80. Since the battery 60 provides electric power to the electrical component 80 and is not being charged. The voltage measured by the voltage-sensing device 106 is the voltage of the battery 60 only. In the off mode, and in the presence of an electrical component 80 which is turned on, the battery 60 is drained after some time. The time to drain the battery 60 depends on the load of the electrical component 80 and the capacity of the battery 60.

**[0062]** When a vehicle is started by a driver, for example by activating an ignition key, the engine 20, starter motor 70 and alternator 30 are said to be in a cranking state or undergoing a cranking event. With reference to Figure 3B, the diagram shows the same vehicle's electric subsystems of Figure 3A. Figure 3B also shows the current flowing as solid black lines. During a cranking event, the battery 60 provides power to the starter motor 70 as indicated by the solid line between the positive battery terminal 62 and the starter motor 70. As the starter motor 70 is activated and engages the flywheel 28 as discussed above, the crankshaft of the engine rotates. As the alternator 30 is mechanically coupled to the crankshaft, the

alternator shaft also rotates, and the alternator 30 starts generating some electricity. During cranking any electrical component 80 which is turned on consumes electric power from both the battery 60 and/or the alternator 30 depending on electric load of the electrical component 80. The voltage measured at the positive battery terminal 62, by the voltage-sensing device 106, during cranking is termed the "cranking voltage". The cranking voltage fluctuates as the starter motor 70 starts and as the alternator 30 starts generating electricity. As discussed below, there is a point at which the cranking voltage is at a minimum value termed the "minimum cranking voltage" and another point at which the cranking voltage is at a maximum value termed the "maximum cranking voltage."

**[0063]** When the engine 20 starts, the cranking event is terminated and the starter motor 70 is both disengaged from the engine 20 and is no longer powered up. This is illustrated in Figure 3C. After cranking is terminated, the voltage measured at the positive battery terminal 62, by the voltage-sensing device 106, is termed the "device voltage". As shown in Figure 3C, there are solid black lines between the alternator 30 and the positive battery terminal 62 as well as between the positive battery terminal 62 and the electrical component 80 indicating that the electrical components 80 may be consuming electric power from both the alternator 30 and the battery 60.

**[0064]** An alternator undercharging condition eventually leads to depletion of the vehicle battery. As a result, there may not be enough power in the vehicle battery to start the starter motor and thus the vehicle. Consequently, delivery of goods cannot be made or are delayed until the vehicle battery is either charged or replaced. The result of failing to deliver some goods on time may result in heavy losses. For example, a truck carrying perishable food items must be delivered on time or the food might devour. One simple solution to avoid a situation where the alternator is undercharging the vehicle battery is to periodically replace the alternator thus ensuring that the vehicle has a relatively new alternator in good working condition. Replacement of an alternator in a vehicle adds to the cost of operating and maintaining the vehicle. If replaced too early or unnecessarily, it adds a cost that could have been avoided. Therefore, the idea of preemptively replacing a healthy alternator is not ideal. It is therefore desirable to predict alternator failures before they cause a vehicle to be stranded and/or a delivery not to be made on time.

**[0065]** The inventors have observed and determine that certain characteristics of the cranking voltage and the device voltage may indicate a case of an alternator undercharging condition. Accordingly, methods and systems for detecting alternator undercharging conditions, are better understood once the voltage patterns observed during and after a cranking event are explained as is done with reference to Figure 4.

**[0066]** With reference to Figure 4, there is shown a graph depicting voltage measured at the positive battery terminal (to which the output of the alternator is connect-

ed) during and after a cranking event. The horizontal axis represents time, while the vertical axis represents the voltage measured at the positive battery terminal 62. Before the cranking event, the measured voltage was around 12.6V. This represents the voltage at the positive battery terminal 62 with the alternator 30 not generating any electrical power. At time 90, the cranking event starts. The cranking voltage remains at the initial cranking voltage 49, which is around 12.6V. As the starter motor 70 draws a large amount of current from the vehicle battery in order to start, the battery output voltage drops significantly. As discussed, the output voltage of the battery during a cranking event is considered a cranking voltage. As can be seen, the cranking voltage drops until it is at a minimum cranking voltage 51 (which is around 9.8V approximately). As the starter motor 70 starts rotating and gains momentum, the current drawn by the starter motor 70 drops and accordingly the cranking voltage rises. Additionally, as the starter motor 70 rotates at a faster speed, so does the crank shaft of the engine, and so does the alternator shaft. As a result, the alternator 30 starts producing electricity, and the cranking voltage rises. As shown between the time 90 and the time 92.

**[0067]** At the time 92, the cranking voltage reaches a maximum cranking voltage 52. The maximum cranking voltage 52 is also the last cranking voltage measured. Once the engine has fully started, cranking is stopped, and the starter motor 70 is disengaged from the engine both electrically and mechanically. At this point, the voltage measured at the positive battery terminal 62 is the device voltage. The first device voltage 54 has the value of approximately 13.2V. At this point, the regulator 38 may increase the power provided to the electromagnet of the rotor 32 to bring the alternator output voltage to 13.6V so that it is higher by 1V than the battery output voltage, which was measured to be 12.6V before the cranking event. The device voltage reaches a maximum device voltage 56 at a time 96.

**[0068]** With reference to Figure 4, a few observations can be made. Firstly, the maximum cranking voltage 52 and the maximum device voltage 56 are substantially equal. In reality they may not be identical and may be off by 0.1V or so. Secondly, the time period between the maximum cranking voltage 52 and the maximum device voltage 56 is relatively short. For example, in Figure 4, the maximum cranking voltage 52 took place at approximately 00:29:08 and the maximum device voltage 56 took place at approximately 00:29:23. In other words, it took around 15 seconds after the maximum cranking voltage 52 for the device voltage to reach the maximum device voltage 56.

**[0069]** In vehicles where the alternator is either undercharging or overcharging the battery, the device voltage after cranking follows different patterns.

**[0070]** For example, with reference to Figure 5, there is shown a vehicle charging profile for a vehicle in which the alternator is undercharging the battery. The graph covers a period of over 3 minutes starting with cranking.

When cranking starts, the initial cranking voltage 49 was around 11.4V. At the start of cranking, the measured cranking voltage comprises the battery voltage at the positive battery terminal. As discussed above, a battery voltage value that is lower than the lower battery output voltage limit, indicates an undercharged battery. As cranking proceeds, the starter motor draws current and a minimum cranking voltage 51 is reached. As the starter motor gains momentum and the alternator starts generating electricity, the cranking voltage rises. The maximum cranking voltage 52 has a voltage value of 13.6V, which is a good value for a vehicle electric system including a 12V battery, as discussed above. Cranking ends and the maximum cranking voltage 52 is also the last cranking voltage. Past this point, the engine is in normal operation and the measured voltage is the device voltage. The first observed device voltage 54A is around 12.4V. The second observed device voltage 54B is around 11.3V. The third observed device voltage 54C is around 10.5V. Accordingly, the device voltage is dropping. Since the device voltage is an indication of the alternator output voltage, it can be deduced that the alternator output voltage is below the lower alternator output voltage limit, which for 12V batteries is 13.2V. Therefore, the device voltage pattern of Figure 5 is indicative of an undercharging condition.

**[0071]** With reference to Figure 6, there is shown a vehicle charging profile for a vehicle in which the alternator is overcharging the battery. The profile covers a period of approximately 10 seconds starting with cranking. First, it is observed that the initial cranking voltage 49 is around 15.8V, which is high as it is expected that the battery voltage is at most 12.6V for a 12V battery. As cranking proceeds, the starter motor draws plenty of current and the cranking voltage drops to a minimum cranking voltage 51, which is around 7.6V. As before, the starter motor gains momentum and the alternator starts generating electricity, the cranking voltage rises. The maximum cranking voltage 52 is over 16V, which is high. The engine starts, and the first observed device voltage 54A is around 15V, the second observed device voltage 54B is around 18.5V, and the third observed device voltage 54C is around 19.5V. Subsequent device voltage values 54D, 54E, 54F, 54G and 54H are all around 20V. This voltage profile indicates that the alternator is overcharging the battery.

**[0072]** The duration between the timestamp of the maximum cranking voltage and the timestamp of the maximum device voltage varies with each cranking event. The inventors have analyzed voltage patterns from numerous vehicle electric systems of different makes and models and have observed certain distributions.

**[0073]** Figure 7A shows a histogram 710 of the full distribution of the duration between maximum cranking voltage and maximum device voltage for an International MV having a 6.7L Diesel Cummins engine. It has been observed that in most cranking events, the maximum device

voltage is reached less than 200 seconds after the maximum cranking voltage. A histogram 720 of the duration limited to where the duration between the maximum cranking voltage and the maximum device voltage is less than 200 seconds shows that for an international MV in the majority of cases, the duration between the maximum cranking voltage and the maximum device voltage is less than 50 seconds.

**[0074]** Figure 7B shows a histogram 710 of the full distribution of the duration between maximum cranking voltage and maximum device voltage for a Chevrolet Equinox having a 4 cylinder 1.5L engine. It has been observed that in most cranking events, the maximum device voltage is reached less than 600 seconds after the maximum cranking voltage. A histogram 720 of the duration limited to where the duration between the maximum cranking voltage and the maximum device voltage is less than 200 seconds shows that for a Chevrolet Equinox in the majority of cases, the highest distribution of the duration between the maximum cranking voltage and the maximum device voltage is also less than 50 seconds. For a Chevrolet Silverado, the distribution of the duration between the maximum cranking voltage and the maximum device voltage is shown in Figure 7C. The distribution is somewhat similar to the Chevrolet Equinox.

**[0075]** Figure 7D shows a histogram 710 of the full distribution of the duration between maximum cranking voltage and maximum device voltage for a Dodge Ram having a 2500 3.6L V6 engine. It has been observed that in most cranking events, the maximum device voltage is reached less than 200 seconds after the maximum cranking voltage. A histogram 720 of the duration limited to where the duration between the maximum cranking voltage and the maximum device voltage is less than 200 seconds shows that for a Dodge Ram in the majority of cases, the duration between the maximum cranking voltage and the maximum device voltage is between 100 seconds and 150 seconds.

**[0076]** The above observations relating to the duration between the maximum cranking voltage and the maximum device voltage become relevant when it is correlated with the monitoring of normal, overcharging, and undercharging events. For example, with reference to Figure 8, graphs depicting the number of normal, overcharging, and undercharging events versus the time of the events are shown for a Ford Transit having a 3.5L V6 gasoline engine. The graph 810 depicts normal events, the graph 820 depicts undercharging events, and the graph 830 depicts overcharging events. It can be seen that normal events take place mostly under 2 minutes and generally up to 4 minutes. Undercharging events take place mostly before 3 minutes (180 seconds or approximately 200 seconds). In this graph, there were no overcharging events, and hence the overcharging graph 830 is flat.

**[0077]** The inventors have investigated numerous cases of alternator failure and observed a correlation between some failures and the duration between the max-

imum cranking voltage and the maximum device voltage. Specifically, if the duration between the maximum cranking voltage and the maximum device voltage exceeds an undercharging indication duration threshold, this indicates that an alternator undercharging condition is likely. If the duration between the maximum cranking voltage and the maximum device voltage exceeds the undercharging indication duration threshold repeatedly, then the vehicle operator or a fleet manager needs to be alerted of the potential undercharging condition. As a result, the alternator may be repaired or rebuilt. The described method has additional advantages. For example, some vehicles reduce the alternator voltage during normal operation when the battery is fully charged. As such, solely relying on measuring the alternator output voltage to determine whether an undercharging condition is happening may give false positives on such vehicles. The method described herein predicts potential alternator failures in a reliable manner and does so in advance of the problem affecting the vehicle operation. For example, relying solely on measuring the alternator output voltage may give an indication that the alternator has already failed while in the middle of a trip where service centers may not be nearby. The advantage of the method described herein is that it predicts potential alternator failure within a short duration of starting the vehicle (e.g., within 200 seconds or just over 3 minutes). This gives the operator sufficient time to return and take necessary measures such as replacing the alternator prior to starting a long trip.

**[0078]** In some embodiments, the detected maximum cranking voltages, and maximum device voltages along with their timestamps may be used by an on-board device to compute the time difference between each maximum cranking voltage and a corresponding maximum device voltage. If the time difference between the maximum cranking voltage and the maximum device voltage exceeds a particular threshold, then the on-board device may trigger an alert for the associated vehicle. For example, an indicator in the dashboard may light up and/or an alarm sound may alert the driver of a potential alternator failure. In other embodiments, the maximum cranking voltages, the maximum device voltages, and their associated timestamps are included in telematics data captured from the vehicle using a telematics coupled to the vehicle. The telematics data is gathered by the telematics device and transmitted to a telematics server for analysis. The telematics server may be queried for data on specific vehicles or may be configured to send warnings to a user, such as a fleet manager, alerting them of vehicles with potential undercharging problems, for example.

**[0079]** Figure 9 shows a high-level block diagram of a telematics system 1000. The telematics system 1000 includes a telematics server 130, and (N) telematics devices shown as telematics device 200\_1, telematics device 200\_2...through telematics device 200\_N ("telematics device 200"). The telematics system 1000 may also

include an administration terminal 400. A network 50 may provide connectivity between the telematics devices 200 and the telematics server 130, and between the administration terminal 400 and the telematics server 130. Figure 1 also shows a plurality of (N) assets named as asset 100\_1, asset 100\_2...asset 100\_N ("asset 100"); and a plurality of satellites 700\_1, 700\_2 and 700\_3 ("satellite 700").

**[0080]** The assets 100 shown are in the form of vehicles. For example, the asset 100\_1 is shown as a truck, which may be part of a fleet that delivers goods or provides services. The asset 100\_2 is shown as a passenger car that typically runs on an internal combustion engine (ICE). The asset 100\_3 is shown as an electric vehicle (EV). While the assets have been shown as vehicles, in some examples they may be airborne vehicles such as airplanes, helicopters, or drones. In other examples, the assets may be marine vehicles such as boats, ships, or submarines. In further examples, the assets may be stationary equipment such as industrial machines.

**[0081]** The telematics devices 200 are electronic devices which are coupled to assets 100 and configured to gather asset data from the assets 100. For example, in Figure 9 the telematics device 200\_1 is coupled to the asset 100\_1. Similarly, the telematics device 200\_2 is coupled to the asset 100\_2 and the telematics device 200\_3 is coupled to the asset 100\_3. The components of a telematics device 200 are explained in further detail with reference to Figure 10.

**[0082]** The network 50 may be a single network or a combination of networks such as a data cellular network, the Internet, and other network technologies. The network 50 allows the telematics devices 200 to communicate with the telematics server 130 and allows the administration terminal 400 to communicate with the telematics server 130.

**[0083]** The satellites 700 may be part of a global navigation satellite system (GNSS) and may provide location information to the telematics devices 200. The location information may be processed by a location module on the telematics device 200 to determine the location of the telematics device 200 (and hence the location of the asset 100 coupled thereto). A telematics device 200 that can periodically report an asset's location is termed an "asset tracking device".

**[0084]** A telematics server 130 is an electronic device having a large data store and powerful processing capability. The telematics server 130 may receive telematics data from telematics devices 200, including cranking and device voltages and their timestamps. The telematics server 130 may compute the likelihood of alternator undercharging conditions based on the received voltages and timestamps. The telematics server 130 may also send alerts for alternator undercharging conditions to one or more remote devices.

**[0085]** The administration terminal 400 is an electronic device, which may be used to connect to the telematics server 130 to retrieve data and analytics related to one

or more assets 100. The administration terminal 400 may be a desktop computer, a laptop computer, a tablet, or a smartphone. The administration terminal 400 may run a web browser or a custom application which allows retrieving data and analytics, pertaining to one or more assets 100, from the telematics server 130 via a web interface of the telematics server.

**[0086]** In operation, a telematics device 200 connects to an asset 100 to gather asset data. The asset data may be combined with location data obtained by the telematics device 200 from a location module in communication with the satellites 700 and/or sensor information gathered from sensors in the telematics device 200. The combined data may be termed "telematics data." The telematics device 200 sends the telematics data, over to the telematics server 130 over the network 50. The telematics server 130 may process, aggregate, and analyze the telematics data to generate information about the assets 100 or a fleet of assets. The administration terminal 400 may connect to the telematics server 130, over the network 50, to access the generated information. Alternatively, the telematics server 130 may push the generated information to the administration terminal 400. For example, the asset data may comprise a maximum cranking voltage along with its timestamp and the maximum device voltage along with its timestamp as well as an asset identifier, such as a vehicle type. The telematics server 130 may perform some computations to determine, for the vehicle type, whether an alternator undercharging condition is likely. The telematics server 130 may generate alert information for the particular asset (vehicle) indicating the undercharging condition, if applicable. The alert information may be accessed by the administration terminal 400.

**[0087]** In the attached figures, a telematics device 200 is shown as a separate entity connected with a corresponding asset. It would be, however, apparent to those of skill in the art that other configurations are possible. For example, the telematics device 200 may be integrated with the asset 100 at the time of manufacturing. In other examples, the telematics device may be deployed on an asset but not connected therewith. For example, a telematics device 200 may be deployed in a vehicle and may monitor the vehicle's temperature, location, speed, and direction of travel solely using sensors or peripherals on board the telematics device 200 such as a temperature sensor, a GPS receiver, an accelerometer, and a gyroscope.

**[0088]** Further details relating to the telematics device 200 and how it interfaces with an asset 100 are shown with reference to Figure 10. Figure 10 depicts an asset 100 and a telematics device 200 connected thereto. Selected relevant components of each of the asset 100 and the telematics device 200 are shown. For example, while the asset 100 may be a vehicular asset, only components relevant to gathering asset data are shown in the figure. The asset 100 may have a plurality of electronic control units (ECUs). An ECU is an electronic module which interfaces with one or more sensors for gathering informa-

tion from the asset 100. For example, an oil temperature ECU may contain a temperature sensor and a controller for converting the measured temperature into digital data representative of the oil temperature. Similarly, a battery voltage ECU may contain a voltage sensor for measuring the voltage at the positive battery terminal and a controller for converting the measured voltage into digital data representative of the battery voltage. A typical vehicle may, for example, have around seventy ECUs. For simplicity, only a few of the ECUs 110 are depicted in Figure 2. For example, in the depicted embodiment the asset 100 has three electronic control units including the ECU 110A, the ECU 110B, and the ECU 110C ("ECUs 110"). The ECU 110A, the ECU 110B, and the ECU 110C are shown to be interconnected via a bus, such as a Controller Area Network (CAN) bus 150. ECUs 110 interconnected using a CAN bus send and receive information to one another in CAN frames by placing the information on the CAN bus 150. When an ECU places information on the CAN bus 150, other ECUs 110 receive the information and may or may not consume or use that information. Different protocols are used to exchange information between the ECUs over a CAN bus. For example, ECUs 110 in trucks and heavy vehicles use the Society of Automotive Engineering (SAE) J1939 protocol to exchange information over a CAN bus 150. Most passenger vehicles use the On-Board Diagnostic (OBD) protocol to exchange information between ECUs 110 on their CAN bus 150. In industrial automation, ECUs use a CANOpen protocol to exchange information over a CAN bus 150. An asset 100 may allow access to information exchanged over the CAN bus 150 via an interface port 102. For example, if the asset 100 is a passenger car, then the interface port 102 is most likely an OBD-II port. Data accessible through the interface port 102 is termed the asset data 112. An example of the asset data 112 includes the cranking and device voltages gathered from an ECU coupled to the battery and alternator, as will be described below. In some embodiments, the interface port 102 includes a power interface for providing power to a device connecting thereto.

**[0089]** The telematics device 200 includes a controller 230 coupled to a memory 240, an interface layer 210 and a network interface 220. The telematics device 200 also includes one or more sensors 204 and a location module 206 coupled to the interface layer 210. The telematics device further includes some rudimentary output devices such as an indicator light 292 and a buzzer 294. In some embodiments (not shown), the telematics device 200 may have a dedicated power source or a battery. In other embodiments, the telematics device 200 may receive power directly from the asset 100. The telematics device 200 shown is an example. Some of the depicted components may be optional. For example, some telematics devices may not have a location module 206 and may rely on an external location module for obtaining location data 207. Some telematics devices may not have any sensors 204 and may rely on external sensors for obtain-

ing sensor data 205.

**[0090]** The controller 230 may include one or any combination of a processor, microprocessor, microcontroller (MCU), central processing unit (CPU), processing core, state machine, logic gate array, application-specific integrated circuit (ASIC), field-programmable gate array (FPGA), or similar, capable of executing, whether by software, hardware, firmware, or a combination of such, the actions performed by the controller 230 as described herein.

**[0091]** The indicator light 292 is an electronic peripheral capable of emitting visual light. The indicator light 292 may be a light emitting diode (LED) or another form of light which can be activated either to display a solid light or a flashing light with different duty cycles. The indicator light 292 may be used to indicate an alert condition under control of firmware executed by the controller 230.

**[0092]** The buzzer 294 is an electronic device which produces an audible signal. The buzzer 294 may be a speaker or a piezoelectric transducer. The buzzer 294 may be used to indicate an alert condition under control of firmware executed by the controller 230.

**[0093]** The memory 240 may include read-only-memory (ROM), random access memory (RAM), flash memory, magnetic storage, optical storage, and similar, or any combination thereof, for storing machine-executable instructions and data to support the functionality described herein. The memory 240 is coupled to the controller 230 thus enabling the controller 230 to execute the machine-executable programming instructions stored in the memory 240. The memory 240 may store machine-executable instructions, which when executed by the controller 230, configures the telematics device 200 for receiving asset data 112 from the asset 100 via the asset interface 202, and for receiving sensor data 205 from the sensors 204 and/or location data 207 from the location module 206 via the sensor interface 208. The memory 240 may also contain machine-executable programming instructions for combining asset data 112, sensor data 205 and location data 207 into telematics data 212. Additionally, the memory 240 may further contain instructions which, when executed by the controller 230, configures the telematics device 200 to transmit the telematics data 212 via the network interface 220 to a telematics server 130 over a network 50.

**[0094]** In some embodiments, the memory 240 may contain modules for analyzing the asset data 112 and generate an alert accordingly. For example, the memory 240 may contain modules for analyzing cranking and device voltages and checking whether the alternator is overcharging or undercharging the vehicle's battery. In case an overcharging or an undercharging condition is detected, the firmware modules may activate the indicator light 292, the buzzer 294, or both in order to signal the alert condition.

**[0095]** In some embodiments, the memory may contain firmware modules for receiving alert messages from the telematics server over the network interface 220. For

example, after sending the telematics data 212 to the telematics server, the telematics device 200 may receive, over the network interface 220, an alert message from the telematics server indicating an alert condition related to the operation of the vehicle. For example, the telematics device 200 may receive an alert message indicating that the vehicle coupled to the telematics device 200 is undergoing an alternator undercharging condition. The firmware modules may further configure the telematics device 200 to issue an alert in response to receiving the alert message. The issued alert may be in the form of a sound produced by the buzzer 294 or a light produced by the indicator light 292.

**[0096]** The location module 206 may be a global positioning system (GPS) transceiver or another type of location determination peripheral that may use, for example, wireless network information for location determination. The sensors 204 may be one or more of: a temperature sensor, a pressure sensor, an optical sensor, an accelerometer, a gyroscope, or any other suitable sensor indicating a condition pertaining to the asset 100 to which the telematics device 200 is coupled.

**[0097]** The interface layer 210 includes an asset interface 202 and a sensor interface 208. The sensor interface 208 is configured for receiving sensor data 205 and location data 207 from the sensors 204 and the location module 206, respectively. For example, the sensor interface 208 interfaces with the location module 206 and with the sensors 204 and receives both sensor data 205 and location data 207, respectively, therefrom. The interface layer 210 also includes an asset interface 202 to receive asset data 112 from the asset 100. In the depicted embodiment, the asset interface 202 is coupled to the interface port 102 of the asset 100. In other embodiments where the telematics device 200 is integrated into the asset 100, the asset interface 202 may receive the asset data 112 directly from the CAN bus 150. The asset data 112, received at the telematics device 200, from the asset 100 may be in the form of data messages, such as CAN frames. Asset data 112 may describe one or more of any of: a property, a state, and an operating condition of the asset 100. For example, where the asset 100 is a vehicle, the data may describe the speed at which the vehicle is traveling, a state of the vehicle (off, idle, or running), or an engine operating condition (e.g., engine oil temperature, engine RPM, or a battery voltage). In addition to receiving the asset data 112, in some embodiments the asset interface 202 may also receive power from the asset 100 via the interface port 102. The interface layer 210 is coupled to the controller 230 and provides the asset data 112, sensor data 205, and location data 207 to the controller 230.

**[0098]** The network interface 220 may include a cellular modem, such as an LTE-M modem, CAT-M modem, other cellular modem, Wi-Fi modem, or any other communication device configured for communication via the network 50 with which to communicate with the telematics server 130. The network interface 220 may be used

to transmit telematics data 212 obtained from the asset 100 to the telematics server 130 for a telematics service or other purposes. The network interface 220 may also be used to receive instructions from the telematics server 130 as to how to communicate with the asset 100.

**[0099]** In operation, an ECU 110, such as the ECU 110A, the ECU 110B, or the ECU 110C communicates asset data over the CAN bus 150. Asset data exchanged, between the ECUs 110, over the CAN bus 150 are accessible via the interface port 102 and may be retrieved as asset data 112 by the telematics device 200. The controller 230 of the telematics device receives the asset data 112 via the asset interface 202. The controller 230 may also receive sensor data 205 from the sensor 204 and/or location data 207 from the location module 206 over the sensor interface 208. The controller 230 combines the asset data 112 with sensor and location data into telematics data 212. The controller 230 transmits the telematics data 212 to the telematics server 130 over the network 50 via the network interface 220.

**[0100]** In some embodiments, the telematics device 200 may process the asset data 112, sensor data 205, and/or location data 207 locally. For example, the telematics device 200 may process the cranking and device voltages provided as part of the asset data 112 in order to determine an alternator undercharging condition or an alternator overcharging condition. If an alert condition is detected, the controller 230 may activate an alerting device such as the indicator light 292, the buzzer 294, or both.

**[0101]** Figure 11 is a block diagram of the telematics server 130 including selected software modules which perform the functions described in this disclosure. With reference to Figure 11, the telematics server 130 has a controller 330, a network interface 320 for connecting to the network 50, and a non-transitory memory 340 for storing software modules. The non-transitory memory 340 contains software modules comprised of machine executable instructions which when executed the controller 330 perform analysis of telematics data sent to the telematics server 130 by the plurality of telematics devices 200. For example, the non-transitory memory 340 is shown to contain an analysis module 370 and an alert module 385. The analysis module 370 processes the asset data received at the telematics server 130, such as cranking and device voltages. The alert module 385 may send an alert indicating a particular condition detected by processing the asset data. For example, the analysis module 370 may detect an alternator undercharging condition based on asset data received from a telematics device coupled to a particular vehicle asset. The information and analysis provided by the telematics server 130 may be accessible, over the network 50, for viewing and inspection. The telematics server 130 may, for example, provide a web interface 325 through which telematics data gathered from one or more of the plurality of assets 100, as well as analytics related to the telematics data may be accessed. Alternatively, or additionally,

the telematics server 130 may push telematics data and analytics related to one or more assets 100 to one or more electronic devices such as smartphones running a mobile application. For example, the alert module 385 may push an alert message to a smartphone running a mobile application to alert a fleet manager of an anticipated alternator undercharging condition on a vehicle asset.

**[0102]** The ECUs 110 on an asset may include a voltage-sensing ECU that periodically reads cranking and device voltages and places the voltage values on the asset's shared bus, such as the CAN bus 150 of Figure 10. For example, with reference to Figure 12 which depicts components of a vehicle electrical system as shown above with reference to Figures 3A-3C. The components include the voltage-sensing device 106 described above. Coupled to the voltage-sensing device 106, there is an ECU 110. The ECU 110 directs the voltage-sensing device 106 to periodically read the voltage at the positive battery terminal 62. The ECU 110 also places the read information on the shared vehicle bus so it may be read by a telematics device via the interface port 102.

**[0103]** Figure 13 is a flow chart of a method 1300 a telematics device, the method for identifying a potential alternator undercharging condition, in accordance with embodiments of the present disclosure. At step 1302, the telematics device receives a maximum cranking voltage and a maximum cranking voltage timestamp from an asset interface, such as an asset interface of a motor vehicle. At step 1304, the telematics device receives a maximum device voltage and a maximum device voltage timestamp from the asset interface. At step 1306, the telematics device determines the duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp. Since the maximum device voltage timestamp is greater in value than the maximum cranking voltage timestamp, the duration is computed by subtracting the maximum cranking voltage timestamp from the maximum device voltage timestamp. At step 1308, the telematics device compares the computed duration with an undercharging indicator duration threshold. For example, for certain vehicles the undercharging indicator duration threshold may be 200 seconds, so the telematics device compares the computed duration with 200 seconds. If the computed duration is greater than the undercharging indicator duration threshold, then at step 1310 the telematics device determines a potential alternator undercharging condition. In some embodiments, the method 1300 involves repeating the steps 1302, 1304 and 1306 and determining a potential alternator undercharging condition if the condition at step 1308 is true at least once.

**[0104]** Figure 14 is a flow chart of a method 1400 by a telematics device, the method for identifying a potential alternator undercharging condition, in accordance with other embodiments of the present disclosure. At step 1402, the telematics device receives a maximum cranking voltage and a maximum cranking voltage timestamp

from an asset interface, such as an asset interface of a motor vehicle. At step 1404, the telematics device receives a maximum device voltage and a maximum device voltage timestamp from the asset interface. At step 1406, the telematics device sends the maximum cranking voltage, maximum cranking voltage timestamp, maximum device voltage, and maximum device voltage timestamp to a telematics server. In some embodiments, the steps 1402, 1404 and 1406 are repeated to provide the telematics server with multiple instances that it can use to determine a potential alternator undercharging condition.

**[0105]** Figure 15 is a flow chart of a method 1500 by a telematics server, the method for identifying a potential alternator undercharging condition, in accordance with further embodiments of the present disclosure. At step 1502, the telematics server receives a maximum cranking voltage and a maximum cranking voltage timestamp from a telematics device. At step 1504, the telematics server receives a maximum device voltage and a maximum device voltage timestamp from the telematics device. At step 1506, the telematics server determines the duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp. Since the maximum device voltage timestamp is greater in value than the maximum cranking voltage timestamp, the duration is computed by subtracting the maximum cranking voltage timestamp from the maximum device voltage timestamp. At step 1508, the telematics server compares the computed duration with an undercharging indicator duration threshold. For example, for certain vehicles the undercharging indicator duration threshold may be 200 seconds, so the telematics device compares the computed duration with 200 seconds. If the computed duration is greater than the undercharging indicator duration threshold, then at step 1510 the telematics server determines a potential alternator charging condition.

**[0106]** A telematics device 200 may be powered up when the vehicle is turned on, in which case the telematics device 200 can monitor the vehicle's operating conditions and location while it is in motion. In this disclosure, a vehicle is considered to be turned on when the ignition is on, and the engine is running. For an internal combustion engine, when the engine is running the alternator is also running and generating electric power. Vehicles, however, may undergo certain events or changes while they are parked and while the ignition is off. In order to capture such events, the telematics device 200 needs to be powered-up. However, powering-up the telematics device 200 continuously while the engine is off may drain the vehicle's battery since the alternator will not be running to charge the battery. Accordingly, the telematics device 200 may implement a sleep-wake mechanism in which the telematics device 200 remains in a sleep mode most of the time and periodically wakes up to check certain engine operating conditions.

**[0107]** In sleep mode, the controller 230 may run with a slow clock speed and some modules of the telematics device 200 may be turned off such as the location module

206 and the network interface 220. Running the controller 230 with a slow clock speed (for example 32KHz instead of 1MHz or 10MHz) reduces the electric power consumed by the controller 230. Turning off the network interface 220 including, for example, a cellular modem reduces the electric power consumption of the telematics device 200. Similarly, turning off the location module 206, such as a GPS receiver also reduces the overall consumption of the telematics device 200 while it is in sleep mode. The telematics device 200, cannot monitor many of the vehicle's operating conditions or location while in sleep mode. The controller 230, running at a slow clock speed, cannot execute machine-executable programming instructions which can conduct the full functionality including monitoring all asset data 112. Similarly, since the location module 206 is turned off, the telematics device 200 cannot monitor any location change of the asset 100. Furthermore, since the network interface 220 (or at least the model component thereof) is turned off, the telematics device 200 cannot report any telematics data 212 to the telematics server 130. The telematics device 200 thus needs to wake up periodically to check the status of the engine, the sensors, and the location module to determine if the vehicle's conditions have changed.

**[0108]** The telematics device 200 may implement a mechanism for waking up periodically. For example, the controller 230 may have a periodic timer that may be configured to run and expire periodically. The controller 230 may have an interrupt mechanism that generates an interrupt event when the periodic timer expires. The controller 230 may also be configured to wake up when an interrupt event, such as the periodic timer interrupt event takes place. In wakeup mode, the controller 230 runs at a full clock speed and executes machine-executable programming instructions which conduct the full functionality of the telematics device 200. In the transition from a sleep mode to a wakeup mode, the controller 230 may configure a clock generator coupled thereto to switch from running at a slow clock frequency (such as 32KHz) to a faster frequency (such as 1MHz or 10M Hz). Additionally, the controller 230, in response to the interrupt event, may generate output signals to power up the network interface 220, the location module 206, and any other components which were powered down while in sleep mode. While in wakeup mode the controller 230 may check the status of the engine by checking the read asset data 112, may check the sensor data 205 reported by some sensors 204, or check the location data 207 reported by the location module 206.

**[0109]** Figure 16 is a graph that depicts a power-saving scheme 1600 implemented by a telematics device 200. The horizontal axis of the graph represents time, while the vertical axis represents power consumption. Since power is the product of voltage and current, the vertical axis may also represent the current drawn by the telematics device since the supply voltage may be largely constant. The graph depicts two main power consumption levels. When the telematics device 200 is in sleep mode,

the telematics device 200 consumes electric power at the sleep power consumption level 1602. When the telematics device 200 is in wakeup mode, the telematics device 200 consumes electric power at the regular wakeup power consumption level 1604. Figure 16 depicts three regular wakeup events (hereinafter "regular wakeups") 1613A, 1613B, and 1613C. The regular wakeup 1613A has a wakeup duration 1612A, the regular wakeup 1613B has a wakeup duration 1612B, and the regular wakeup 1613C has a wakeup duration 1612C. Each regular wakeup may be triggered by a periodic event such as a periodic timer expiration interrupt.

**[0110]** At the wakeup time 1610A, the telematics device 200 transitions from sleep mode to wakeup mode. Specifically, at the wakeup time 1610A, the telematics device 200 enters the regular wakeup 1613A. The wakeup time 1610A may be determined by the expiration of a periodic timer. While in wakeup mode, such as while in the regular wakeup 1613A, the controller 230 checks the asset data 112, the sensor data 205, and the location data 207 and may send updates over the network interface 220 to the telematics server 130. At the sleep time 1614A the controller 230 puts the telematics device 200 back into sleep mode. The wakeup duration 1612B of the regular wakeup 1613B begins at the wakeup time 1610B and ends at the sleep time 1614B. The wakeup duration 1612C of the regular wakeup 1613C begins at the wakeup time 1610A and ends at the sleep time 1614A. The wakeup duration 1612A of the regular wakeup 1613A begins at the wakeup time 1610A and ends at the sleep time 1614A. In some embodiments, the wakeup duration 1612A depends on how long the controller 230 takes to check the asset data 112, the sensor data 205, and the location data 207. The wakeup period 1615 is the time between the start of the first wakeup and the start of the next wakeup event. For example, the wakeup period 1615 starts at the wakeup time 1610A and ends at the wakeup time 1610B.

**[0111]** The period between a wakeup time 1610A and a subsequent wakeup time such as 1615B is the wakeup period of the periodic wakeup timer, which is designated as the wakeup period 1615. As shown in Figure 16, the wakeup period 1615A, the wakeup period 1615B, and the wakeup period 1615C are equal and may be referred to as the wakeup period 1615. Each wakeup period 1615 consists of a regular wakeup duration and a sleep duration 1616. The wakeup durations 1612A, 1612B, and 1612C are substantially equal, and may be referred to as the regular wakeup duration 1612. Accordingly, the sleep durations 1616A, 1616B, and 1616C are substantially equal and may be referred to as the sleep duration 1616.

**[0112]** The average power consumption of the telematics device 200 is dependent on the ratio between the regular wakeup duration 1612 and the sleep duration 1616 of a wakeup period 1615. If the regular wakeup duration 1612 is largely fixed as it is the duration that takes the controller 230 to check and assess the asset

data 112, sensor data 205, and location data 207, then lowering the average power consumption for the telematics device 200 is accomplished by increasing the sleep duration 1616, which entails increasing the wakeup period 1615. Increasing the wakeup period 1615 may be done by increasing the period of the wakeup timer. However, increasing the wakeup period 1615 (and accordingly increasing the sleep duration 1616) may lead to missing some events.

**[0113]** When the vehicle is off, the wakeup period 1615 may be relatively long such as every 60 seconds or 30 seconds. A power-saving scheme such as the power-saving scheme 1600 may have a wakeup period of 100ms prior to detecting, by the telematics device 200, of an ignition signal. During a sleep duration 1616, the telematics device 200 is in sleep mode and cannot detect events that are highly varying with time. An example of such events is the voltage fluctuation exhibited by the voltage during a cranking event, such as the one shown in Figure 4. The telematics device 200 executes a power-saving scheme 1600 until the vehicle has been turned on, i.e., until an ignition signal has been detected. The cranking event takes place before the telematics device 200 can detect an ignition signal. Therefore, the cranking event voltages need to be detected while the telematics device 200 is implementing a power-management scheme. It is likely that a cranking event may take place while the telematics device 200 is in a sleep duration 1616. To illustrate this problem, Figure 17 shows a portion of the power-saving scheme 1600 of Figure 16 with the voltage during the cranking even of Figure 4 overlaid on top. As can be seen in Figure 17, the voltage variations during the cranking event take place while the telematics device 200 is in the sleep duration 1616A. As such, none of the minimum cranking voltage 51, the maximum cranking voltage 52 or even the initial device voltage 54 may be detected or captured by the telematics device 200.

**[0114]** The present disclosure proposes a method and system for detecting voltage during a cranking event. The method aims to capture enough voltage readings during the cranking event so as to determine critical voltages such as the maximum cranking voltage, while keeping the power consumption of the telematics device 200 at an acceptable level. A power consumption of an acceptable level is a power consumption which does not drain the vehicle's battery. The proposed method employs a modified power scheme that captures voltage readings at a frequency that is sufficient to detect the maximum cranking voltage.

**[0115]** The method provided herein utilizes micro wakeups in which the telematics device 200 performs micro wakeups to capture some data for processing during regular wakeups. During the micro wakeups, the telematics device may capture sensor data 205 such as motion data during the micro wakeups. The telematics device 200 may also capture battery voltage from pins of the interface port 102. For example, the telematics device 200 may contain an analog to digital converter

(ADC) that converts analog battery voltages detected on power pins of the interface port into digital value. The telematics device 200 powers up a limited number of peripherals during the micro wakeups. Accordingly, the power consumption of the telematics device 200 during the micro wakeups is significantly less than the power consumption of the telematics device 200 during regular wakeups. For example, with reference to Figure 18, there is shown a power management scheme 1800 implementing a wakeup and sleep regime utilizing micro wakeups in the sleep duration between two regular wakeups 1613A and 1613B. The wakeup period 1615 shown may be 100ms as mentioned above. Figure 18 shows a plurality of what is referred to as micro wakeups 1633 each having a micro wakeup duration 1632. The micro wakeups 1633 involve powering up a limited number of peripherals in the telematics device 200 such that certain data can be gathered and cached (buffered). Accordingly, the micro wakeups 1633 consume significantly less power than regular wakeups. For capturing cranking voltage values, the micro wakeups 1633 involve the controller 230 getting out of slow clocking mode and polling the power pins of the interface port 102 for voltage values. Once a voltage reading is obtained, the voltage reading is stored in a voltage data buffer in the memory 240 of the telematics device 200.

**[0116]** In Figure 8, nine micro wakeup durations are shown between the regular wakeups 1613A and 1613B. In other words, every 10<sup>th</sup> micro wakeup is a regular wakeup. The power consumption of the telematics device 200 during the micro wakeups is shown as the micro wakeup power consumption level 1606, which is higher than the sleep power consumption level 1602 but still significantly lower than the regular wakeup power consumption level 1604. Accordingly, the micro wakeups do not drain the vehicle battery at the same rate as regular wakeups would.

**[0117]** When a cranking event is concluded and the vehicle is turned on, the vehicle is in normal operation as discussed above. When the vehicle is in normal operation, i.e., the alternator is running and charging the battery, then the telematics device exits the power-saving scheme and is fully on. When the telematics device 200 is fully on, the voltage readings captured and buffered during the cranking event may be retried and sent over the network interface 220 to the telematics server. Figure 19 shows the voltage fluctuations encountered during a cranking event, superimposed on the power-saving scheme 1600. As can be seen from Figure 19, the cranking voltage may be sampled at every micro wakeup 1633. As a result, most relevant cranking voltages are captured. This includes the initial cranking voltage 49, the minimum cranking voltage 51, and the maximum cranking voltage 52. The initial device voltage 54 is also captured. As shown in Figure 19, the telematics device 200 remains in fully powered mode when the vehicle exits the cranking event.

**[0118]** Figure 20 depicts a method 2000, by a telemat-

ics device, for determining a potential alternator charging condition in accordance with embodiments of the present disclosure.

**[0119]** At step 2010, the telematics device 200 enters sleep mode. This may refer to exiting a regular wakeup, such as the regular wakeup 1613A and entering into sleep mode for a sleep duration 1616.

**[0120]** At step 2020, the telematics device 200 performs a plurality of micro wakeups, such as the micro wakeups 1633, during the sleep duration 1616.

**[0121]** At step 2030, the telematics device captures a first plurality of voltage values corresponding to the micro wakeups. For example, with reference to Figure 19, during each of the micro wakeups 1633, the telematics device 200 performs a voltage measurement. With reference to the cranking voltage values, the voltage readings during the micro wakeups 1633 are able to capture most of the important voltage values during the cranking event. For example, in the depicted example, the initial cranking voltage 49 is captured in the second micro wakeup 1633B. The minimum cranking voltage 51, or a value closer thereto, is captured during the third micro wakeup 1633C. The maximum cranking voltage 52 takes place between the two micro wakeups 1633G and 1633H. Accordingly, the maximum cranking voltage 52 may be determined as the higher of the two readings taken at the micro wakeup 1633G and the micro wakeup 1633H.

**[0122]** At step 2040, the telematics device 200 may perform a regular wakeup 1613B, which is similar to the regular wakeup 1613A.

**[0123]** At step 2050, the telematics device 200 checks for an ignition signal. Checking for an ignition signal may involve examining one or more messages on the CAN bus 150. If no ignition signal is detected, then the regular wakeup 1613B ends and control goes back to step 2010 wherein the telematics device 200 enters into sleep mode again. If, however, an ignition signal is detected then control goes to step 2060.

**[0124]** At step 2060, the telematics device extends the regular wakeup 1613B and remains in fully powered mode, as shown in Figure 19. This is due to the fact that the vehicle is on and is capable of powering the telematics device 200. Additionally, now that the vehicle is on, more asset data 112 from the engine will be sent to the telematics device 200 over the interface port 102. The asset data 112 is available at a rate that requires that the telematics device 200 be fully powered to process the asset data 112.

**[0125]** At step 2070, the telematics device 200 has determined, based on the ignition signal detected at step 2050, that the cranking event has been concluded. Accordingly, the telematics device 200 determines that the first plurality of voltage values captured during the micro wakeups comprise a plurality of cranking voltage values. The telematics device 200 determines a maximum cranking voltage 52 and a corresponding maximum cranking voltage timestamp from the first plurality of voltage values.

**[0126]** At step 2080, the telematics device 200 has determined that the cranking event has been concluded. Accordingly, voltage readings at the battery terminals taken subsequent to the cranking event comprise device voltages. The telematics device 200 captures a second plurality of voltage values at the battery terminals. In some embodiments, the telematics device 200 captures device voltage values in a periodic manner as long as the vehicle is on, i.e., the ignition is on. In some embodiments, the telematics device captures device voltage values in a periodic manner at a first frequency when the ignition is on, and at a second frequency when the engine is running (i.e., the RPM is > 0). The second plurality of voltage values may comprise a plurality of values captured within a predetermined duration of the conclusion of the cranking event. For example, with reference to Figure 8, it can be seen that the undercharging events take place under 8 minutes. Most undercharging events take place in the first 4 minutes since the beginning of cranking. As such, the second plurality of voltage values may be the voltage values captured since the conclusion of the cranking event and for a predetermined duration.

**[0127]** At step 2090, the telematics device 200 determines a maximum device voltage and a corresponding maximum device voltage timestamp from the second plurality of voltage values. For example, the telematics device 200 may compare the values of the voltages in the second plurality of voltage values, and select the maximum voltage value as the maximum device voltage. The time at which the maximum device voltage was captured is the corresponding maximum device voltage timestamp.

**[0128]** At step 2092, the telematics device 200 determines the duration between the maximum cranking voltage and the maximum device voltage. For example, the telematics device 200 may subtract the maximum cranking voltage timestamp from the maximum device voltage timestamp to obtain the duration therebetween. If the duration between the maximum cranking voltage and the maximum device voltage exceeds an undercharging indicator duration threshold, the telematics device 200 determines a potential alternator undercharging condition.

**[0129]** The power-saving scheme shown in Figure 17 may have a wakeup period 1615 that is of the order of several seconds, such as 10 seconds or 30 seconds. A typical cranking event may last approximately 5 to 10 seconds. Therefore, as shown in Figure 17, the cranking events may be missed. The implementation of micro-wakeups as shown in Figure 19 addresses the problem. However, at a slow wakeup period of 10 seconds for a cranking event that may last 10 seconds, the number of voltage readings gathered may be quite large. For example, if the micro wakeups are every 10ms, there will be 100 readings per second. For a cranking event that lasts 10 seconds, there may be 1000 readings. In some cases, the determination of whether an undercharging event has taken place may need to be performed at the telematics server 130. One reason for that is that is for

keeping the data stored in the telematics database 135 for use in other analytics. Another reason is to use the data to try different scenarios. Sending one thousand voltage readings at one point may be excessive and slow.

**[0130]** A regular wakeup period 1615 of several seconds is inadequate for some events that need to be detected while a vehicle is off, such as sensor data 205. Accordingly, some telematics devices 200 may have a regular wakeup period of 100ms, or a wakeup frequency of 10Hz. Another telematics device 200 may have a regular wakeup duration of 1 second. This is illustrated in Figure 21 in relation to cranking and post-cranking voltage. In Figure 21, there are shown 7 regular wakeups 1613A, 1613B, 1613C, 1613D, 1613E, and 1613F. Each of the regular wakeups 1613 has a wakeup period of 1615. In the depicted example the wakeup period 1615 may be 1 second. The cranking event may take 5 seconds. Accordingly, in the depicted embodiment, the telematics device 200 may gather five voltage readings during the cranking events. At each regular wakeup 1613, the telematics device 200 sends the cranking voltage reading to the telematics server 130. As shown, the gathered voltage readings do not include the minimum cranking voltage 51 or the maximum cranking voltage 52. Accordingly, important cranking voltage values are missed. The inventors have reduced the wakeup period 1615 to 100ms, i.e., used a wakeup frequency of 10Hz. While the gathered voltage readings have improved in accuracy, it has been found that a frequency of 10Hz is still insufficient to account for the variability in the voltage during a cranking event, and some values such as the minimum cranking voltage 51 and the maximum cranking voltage 52 were not captured. Reducing the regular wakeup period 1615 further would create a number of problems. Firstly, the average power consumption of the telematics device 200 would increase. Secondly, powering up the network interface 220, which is generally a cellular modem, and connecting to a network 50 takes more than 10ms. Accordingly, a micro wakeup scheme in which the voltage values are read and buffered, then sent over to the server 130 during regular wakeups 1613 is proposed as shown in Figure 22.

**[0131]** Figure 22 depicts a power-saving scheme that implements regular wakeups 1613 at a frequency of around 10Hz and micro wakeups 1633 with a frequency of around 100Hz. Voltage readings gathered during the micro wakeups 1633 are buffered on the telematics device 200, for example in the memory 240. During regular wakeups 1613, the telematics device 200 sends the buffered voltage readings, captured during the micro wakeups, to the telematics server 130. In the depicted embodiment, the minimum cranking voltage 51 is captured among the many voltage readings captured during the micro wakeups 1633 between the regular wakeup 11613B and 1613C. The voltage readings captured between the regular wakeup 1613B and the regular wakeup 1613C are sent to the telematics server during the regular wakeup 1613C. Similarly, the maximum cranking voltage

52 is among the voltage readings captured during the micro wakeups that take place between the regular wakeup 1613D and the regular wakeup 1613E. The voltage readings captured during the micro wakeups that take place between the regular wakeup 1613D and the regular wakeup 1613E are sent by the telematics device 200 to the telematics server 130 during the regular wakeup 1613C.

**[0132]** The telematics server 130 receives the voltage readings during the regular wakeups 1613. The telematics server 130 buffers the voltage readings until an ignition event is detected, discarding older values. The telematics server 130 may discard voltage readings captured for more than a duration typical of a cranking event. For example, the telematics server 130 may retain data voltage readings captured in the 10 seconds prior to the ignition event and discard any earlier events. The telematics server 130 analyzes the voltage readings in the duration prior to an ignition signal to determine the minimum cranking voltage 51 and the maximum cranking voltage 52.

**[0133]** Upon detection of an ignition signal, the telematics device 200 extends a regular wakeup, such as the regular wakeup 1613F and continues to capture voltage readings and sends them to the telematics server 130. The telematics server 130 determines the maximum device voltage 56. Subsequent to that the telematics server 130 determines the difference between the timestamp of the maximum cranking voltage 52 and the maximum device voltage 56. Based on the duration between the maximum cranking voltage 52 and the maximum device voltage 56, the telematics server 130 determines whether the alternator is undercharging the battery.

**[0134]** Figure 23 is a message sequence diagram illustrating a method 2500 by a telematics system including a telematics device 200 and a telematics server 130, in accordance with embodiments of the present disclosure.

**[0135]** At step 2502 the telematics device 200 captures and buffers voltage readings during micro wakeups 1633.

**[0136]** At step 2504, the telematics device 200 sends the buffered voltage readings during a regular wakeup 1613. The steps 2502 may be repeated to capture more than one plurality of voltage readings between two successive regular wakeups.

**[0137]** At step 2506, the telematics server 130 saves the voltage readings received from the telematics device. The voltage readings comprise at least one plurality of voltage readings captured during micro wakeups 1633 between a first regular wakeup and a second regular wakeup. The at least one plurality of voltage readings may comprise more than one plurality of voltage readings each captured during micro wakeups between a first regular wakeup and a second regular wakeup subsequent to the first regular wakeup. For example, the more the at least one plurality of voltage readings may comprise: the plurality of voltage readings captured during the micro wakeups 1633 between the first regular wakeup 1613A

and the second regular wakeup 1613B, the plurality of voltage readings captured during the micro wakeups 1633 between the second regular wakeup 1613B and the third regular wakeup 1613C, and so on.

5 **[0138]** At step 2506, the telematics server 130 saves the at least one plurality of voltage readings. The telematics server 130 may save the at least one plurality of voltage readings into memory, persistent storage, or the telematics database 135.

10 **[0139]** The steps 2502, 2504, and 2506 are repeated. If the telematics device 200 detects an ignition signal from the vehicle to which it is coupled, then the steps 2508, 2510, 2512, and 2514 are executed. Conversely, if no ignition signal is detected, then the step 2516 is executed.

15 **[0140]** At step 2508, the telematics device 200 sends the ignition signal indicator to the telematics server 130.

20 **[0141]** At step 2510, and in response to receiving the ignition signal indicator, the telematics server 130 determines the maximum cranking voltage from the buffered voltage readings. Knowing that the cranking event takes place before the ignition signal, the telematics server 130 examines the stored at least one plurality of voltage readings captured in the preceding cranking duration. For example, if it is estimated that a cranking event lasts 5 to 10 seconds, the telematics server 130 examines the at least one plurality of voltage readings captured in the preceding 10 seconds. The telematics server 130 designates the highest voltage reading during the cranking duration as the maximum cranking voltage.

25 **[0142]** At step 2510, the telematics device 200 sends a plurality of device voltage readings to the telematics server 130.

30 **[0143]** At step 2514, the telematics server 130 determines a maximum device voltage from the plurality of device voltage readings. Determining the maximum device voltage may be done over a period of time, such as 5 minutes or 10 minutes. For example, as shown in Figure 8, most undercharging events take place under 10 minutes. Therefore, the telematics server 130 examines device voltage readings for up to 10 minutes since receiving the ignition signal. The maximum device voltage of the plurality of device voltage readings in the period of time since the ignition signal was received is designated as the maximum device voltage.

35 **[0144]** Subsequent to step 2514, the telematics server 130 may perform steps 1508 and 1510 of Figure 15, the description of which is not duplicated here for brevity.

40 **[0145]** Step 2516 is executed if no ignition signal is received from the telematics device 200. At step 2516, the telematics server 130 discards a plurality of voltage readings captured more than a duration of cranking event ago. For example, if the cranking event lasts 10 seconds, then in the absence of an ignition event, the telematics server 130 removes all voltage readings older than 10 seconds.

45 **[0146]** It should be recognized that features and aspects of the examples provided above can be combined

without departing from the scope of the invention, as defined in the appended claims.

## Claims

1. A method by a telematics device, the method for predicting an alternator failure in a motor vehicle, the method comprising:

entering into a sleep mode, then performing a plurality of micro wakeups during the sleep mode;  
capturing a first plurality of voltage values corresponding to the plurality of micro wakeups;  
waking up from the sleep mode and checking for an ignition signal;  
if the ignition signal is detected:

determining a maximum cranking voltage and a maximum cranking voltage timestamp from the first plurality of voltage values;

capturing a second plurality of voltage values;

determining a maximum device voltage and a maximum device voltage timestamp from the second plurality of voltage values; and  
determining a potential alternator undercharging condition if a duration between the maximum cranking voltage timestamp and the maximum device voltage timestamp is greater than an undercharging indicator duration threshold.

2. The method of claim 1, wherein performing the plurality of micro wakeups comprises powering up a limited number of peripherals of the telematics device.

3. The method of claim 1, wherein capturing the first plurality of voltage values comprises measuring a voltage at a battery terminal of the motor vehicle in each micro wakeup of the plurality of micro wakeups.

4. The method of claim 1, wherein waking up from the sleep mode comprises powering up most peripherals of the telematics device.

5. The method of claim 1, wherein checking for the ignition signal comprises checking for one or more messages received over an interface port of the motor vehicle indicating that ignition is turned on in the motor vehicle.

6. The method of claim 1, wherein determining the maximum cranking voltage and the maximum cranking voltage timestamp from the first plurality of voltage values comprises:

determining a maximum voltage value of the first plurality of voltage values; and  
determining a corresponding maximum voltage value timestamp.

7. The method of claim 1, wherein capturing the second plurality of voltage values comprises measuring a voltage at a battery terminal of the motor vehicle subsequent to receiving the ignition signal.

8. The method of claim 1, wherein capturing the second plurality of voltage values is done for a predetermined duration after detecting the ignition signal.

9. The method of claim 1, wherein determining the maximum device voltage and the maximum device voltage timestamp from the second plurality of voltage values comprises:

determining a maximum voltage value of the second plurality of voltage values; and  
determining a corresponding maximum voltage value timestamp.

10. The method of claim 1, wherein the undercharging indicator duration threshold is 200 seconds.

11. A telematics device coupled to a motor vehicle, the telematics device comprising:

a controller;  
an asset interface coupled to the controller; and  
a memory storing machine-executable instructions which, when executed by the controller, configure the telematics device to perform the method of any one of claims 1 to 10.

## Patentansprüche

1. Verfahren für eine Telematikvorrichtung, wobei das Verfahren zur Vorhersage einer Lichtmaschinenstörung in einem Kraftfahrzeug bestimmt ist, wobei das Verfahren umfasst:

Eintreten in einen Schlafmodus und dann Durchführen einer Mehrzahl von Mikro-Aufweckvorgängen während des Schlafmodus;  
Erfassen einer ersten Mehrzahl von Spannungswerten, die der Mehrzahl von Mikro-Aufweckvorgängen entsprechen;  
Aufwachen aus dem Schlafmodus und Prüfen auf ein Zündsignal;  
wenn das Zündsignal detektiert wird:

Bestimmen einer maximalen Anlassspannung und eines Zeitstempels für die maximale Anlassspannung aus der ersten Mehr-

- zahl von Spannungswerten;  
Erfassen einer zweiten Mehrzahl von Spannungswerten;  
Bestimmen einer maximalen Vorrichtungsspannung und eines Zeitstempels für die maximale Vorrichtungsspannung aus der zweiten Mehrzahl von Spannungswerten und  
Bestimmen eines potenziellen Unterladungszustands der Lichtmaschine, wenn eine Dauer zwischen dem Zeitstempel für die maximale Anlassspannung und dem Zeitstempel für die maximale Vorrichtungsspannung über einem Schwellenwert für die Dauer des Indikators für die Unterladung liegt.
2. Verfahren nach Anspruch 1, wobei die Durchführung der Mehrzahl von Mikro-Aufweckvorgängen ein Inbetriebsetzen einer begrenzten Anzahl von Peripherievorrichtungen der Telematikvorrichtung umfasst.
3. Verfahren nach Anspruch 1, wobei das Erfassen der ersten Mehrzahl von Spannungswerten das Messen einer Spannung an einem Batteriepol des Kraftfahrzeugs bei jedem Mikro-Aufweckvorgang der Mehrzahl von Mikro-Aufweckvorgängen umfasst.
4. Verfahren nach Anspruch 1, wobei das Aufwachen aus dem Schlafmodus ein Inbetriebsetzen der meisten Peripherievorrichtungen der Telematikvorrichtung umfasst.
5. Verfahren nach Anspruch 1, wobei das Prüfen auf das Zündsignal ein Prüfen auf eine oder mehrere Nachrichten umfasst, die über einen Schnittstellenanschluss des Kraftfahrzeugs empfangen werden und anzeigen, dass die Zündung im Kraftfahrzeug eingeschaltet ist.
6. Verfahren nach Anspruch 1, wobei das Bestimmen der maximalen Anlassspannung und des Zeitstempels für die maximale Anlassspannung aus der ersten Mehrzahl von Spannungswerten Folgendes umfasst:
- Bestimmen eines maximalen Spannungswertes der ersten Mehrzahl von Spannungswerten und Bestimmen eines entsprechenden Zeitstempels für den maximalen Spannungswert.
7. Verfahren nach Anspruch 1, wobei das Erfassen der zweiten Mehrzahl von Spannungswerten ein Messen einer Spannung an einem Batteriepol des Kraftfahrzeugs nach dem Empfang des Zündsignals umfasst.
8. Verfahren nach Anspruch 1, wobei das Erfassen der zweiten Mehrzahl von Spannungswerten für eine vorbestimmte Dauer nach dem Detektieren des Zündsignals erfolgt.
9. Verfahren nach Anspruch 1, wobei das Bestimmen der maximalen Vorrichtungsspannung und des Zeitstempels der maximalen Vorrichtungsspannung aus der zweiten Mehrzahl von Spannungswerten Folgendes umfasst:
- Bestimmen eines maximalen Spannungswertes der zweiten Mehrzahl von Spannungswerten und  
Bestimmen eines entsprechenden Zeitstempels für den maximalen Spannungswert.
10. Verfahren nach Anspruch 1, wobei der Schwellenwert für die Dauer des Indikators für die Unterladung 200 Sekunden beträgt.
11. Telematikvorrichtung, die mit einem Kraftfahrzeug gekoppelt ist, wobei die Telematikvorrichtung Folgendes umfasst:
- eine Steuereinheit;  
eine mit der Steuereinheit gekoppelte Asset-Schnittstelle und  
einen Speicher, der maschinenausführbare Anweisungen speichert, die, wenn sie von der Steuereinheit ausgeführt werden, die Telematikvorrichtung so konfigurieren, dass sie das Verfahren nach einem der Ansprüche 1 bis 10 durchführt.

### Revendications

1. Méthode par un système télématique, la méthode étant destinée à prédire une panne d'alternateur dans un véhicule motorisé, la méthode comprenant :

l'entrée dans un mode de veille, puis la réalisation d'une pluralité de micro-réveils pendant le mode de veille ;  
la capture d'une première pluralité de valeurs de tension correspondant à la pluralité de micro-réveils;  
la sortie du mode veille et la détection d'un signal d'allumage;  
si le signal d'allumage est détecté :

la détermination d'une tension de démarrage maximum et d'un horodatage de tension de démarrage maximum à partir de la première pluralité de valeurs de tension ;  
la capture d'une seconde pluralité de valeurs de tension ;  
la détermination d'une valeur de tension

- maximum et d'un horodatage de tension de dispositif maximum à partir de la seconde pluralité de valeurs de tension ; et la détermination d'une condition potentielle de sous-charge d'alternateur si une durée entre l'horodatage de tension de démarrage maximum et l'horodatage de tension de dispositif maximum est supérieure à un seuil de durée indicateur de sous-charge.
2. Méthode selon la revendication 1, dans laquelle la réalisation de la pluralité de micro-réveils comprend la mise sous tension d'un nombre limité de périphériques du dispositif télématique.
3. Méthode selon la revendication 1, dans laquelle la capture de la première pluralité de lectures de tension comprend la mesure d'une tension sur une borne de batterie du véhicule motorisé dans chaque micro-réveil de la pluralité de micro-réveils.
4. Méthode selon la revendication 1, dans laquelle la sortie du mode de veille comprend la mise sous tension de la plupart des périphériques du dispositif télématique.
5. Méthode selon la revendication 1, dans laquelle la vérification du signal d'allumage comprend la vérification d'un ou de plusieurs messages reçus via un port d'interface du véhicule motorisé indiquant que l'allumage est activé dans le véhicule motorisé.
6. Méthode selon la revendication 1, dans laquelle la détermination de la tension de démarrage maximum et de l'horodatage de tension de démarrage maximum à partir de la première pluralité de valeurs de tension comprend :
- la détermination d'une valeur de tension maximum de la première pluralité de valeurs de tension ; et  
la détermination d'un horodatage correspondant de valeur de tension maximum.
7. Méthode selon la revendication 1, dans laquelle la capture de la seconde pluralité de valeurs de tension comprend la mesure d'une tension sur une borne de batterie du véhicule motorisé ultérieurement à la réception du signal d'allumage.
8. Méthode selon la revendication 1, dans laquelle la capture de la seconde pluralité de valeurs de tension est réalisée pendant une durée prédéterminée après la détection du signal d'allumage.
9. Méthode selon la revendication 1, dans laquelle la détermination de la tension de dispositif maximum et de l'horodatage de tension de dispositif maximum
- à partir de la seconde pluralité de lectures de tension comprend :
- la détermination d'une valeur de tension maximum de la seconde pluralité de lectures de tension ; et  
la détermination d'un horodatage correspondant de valeur de tension maximum.
10. Méthode selon la revendication 1, dans laquelle le seuil de durée d'indicateur en sous-charge est de 200 secondes.
11. Dispositif télématique couplé à un véhicule motorisé, le dispositif télématique comprenant :
- un contrôleur;  
une interface de ressources couplée au contrôleur; et  
une mémoire stockant des instructions exécutables par machine qui, lorsqu'elles sont exécutées par le contrôleur, configurent le dispositif télématique afin qu'il réalise la méthode selon une quelconque des revendications 1 à 10.
