(57) **ABSTRACT**

A semiconductor device includes a clock gating circuit and a control circuit. The clock gating circuit outputs a gated clock signal based on a clock signal. Transitions of the clock signal are output in the gated clock signal in response to a clock enable signal having an enable value and are disabled from being output in the gated clock signal in response to the clock enable signal having a disable value. The control circuit includes a first portion that operates based on the clock signal. The first portion sets the clock enable signal to the disable value in response to a disable control and sets the clock enable signal to the enable value in response to a wakeup control. The control circuit includes a second portion that operates based on the gated clock signal. The second portion provides the disable control to the first portion during an operation.

METHOD AND APPARATUS FOR POWER SAVING IN SEMICONDUCTOR DEVICES

RELATED APPLICATION

This application is a bypass continuation of International Application No. PCT/CN2021/095709, filed on May 25, 2021. The entire disclosure of the prior application is hereby incorporated by reference in its entirety.

TECHNICAL FIELD

The present application describes examples generally related to semiconductor devices.

BACKGROUND

Semiconductor devices, such as semiconductor memory devices, semiconductor computing devices, and the like, may have significant power consumption. For numerous reasons, it is typically desirable to reduce the power consumption of the semiconductor devices.

In the field of memory devices, semiconductor memory devices can be categorized into volatile memory devices and non-volatile memory devices. The volatile memory devices can lose data when power is off. The non-volatile memory devices can retain stored data even when power is disconnected. To achieve higher data storage density, semiconductor manufacturers developed vertical device technologies, such as three dimensional (3D) NAND flash memory technology, and the like. 3D NAND flash memory device is a kind of non-volatile memory device.

SUMMARY

Aspects of the disclosure provide a semiconductor device that includes a clock gating circuit and a control circuit. The clock gating circuit outputs a gated clock signal based on a clock signal. Transitions of the clock signal are output in the gated clock signal in response to a clock enable signal having an enable value and are disabled from being output in the gated clock signal in response to the clock enable signal having a disable value. The control circuit includes a first portion that operates based on the clock signal. The first portion sets the clock enable signal to the disable value in response to a disable control and sets the clock enable signal to the enable value in response to a wakeup control. The control circuit includes a second portion that operates based on the gated clock signal. The second portion provides the disable control to the first portion during an operation.

Aspects of the disclosure also provide a semiconductor memory device. The semiconductor memory device includes a memory cell array having a block of memory cells and peripheral circuitry coupled with the memory cell array. The peripheral circuitry includes a microcontroller unit (MCU). The MCU includes a clock gating circuit, a polling module and a processing core. The clock gating circuit outputs a gated clock signal based on a clock signal. Transitions of the clock signal are output in the gated clock signal in response to a clock enable signal having an enable value and are disabled from being output in the gated clock signal in response to the clock enable signal having a disable value. The polling module operates based on the clock signal and sets the clock enable signal to the disable value in response to a disable control and sets the clock enable signal to the enable value in response to a wakeup control. The processing core operates based on the gated clock signal.

2

The processing core provides the disable control to the polling module during an operation.

Aspects of the disclosure also provide a method for power saving in a microcontroller unit (MCU). The method includes receiving, by a first portion of the MCU, a disable control from a second portion of the MCU, and disabling, by the first portion of the MCU, signal transitions in a gated clock signal that is provided to the second portion of the MCU in response to the disable control. Further, the method includes enabling, by the first portion of the MCU, the signal transitions in the gated clock signal in response to a wakeup control.

BRIEF DESCRIPTION OF THE DRAWINGS

Aspects of the present disclosure can be best understood from the following detailed description when read with the accompanying figures. It is noted that, in accordance with the standard practice in the industry, various features are not drawn to scale. In fact, the dimensions of the various features may be increased or reduced for clarity of discussion.

FIG. 1 shows a block diagram of a semiconductor device according to some examples of the disclosure.

FIG. 2 shows a block diagram of a semiconductor memory device according to some examples of the disclosure.

FIG. 3 shows a cross-sectional view of a semiconductor memory device, and a schematic symbol of a memory cell string according to some examples of the disclosure.

FIG. 4 shows a table of wakeup source priorities according to some examples of the disclosure.

FIG. 5 shows a plot for illustrating signals in a control circuit according to some examples of the disclosure.

FIG. 6 shows a change from a first firmware control flow to a second firmware control flow according to some examples of the disclosure.

FIG. 7 shows a flow chart outlining a process according to some examples of the disclosure.

FIG. 8 shows a block diagram of a memory system device according to some examples of the disclosure.

DETAILED DESCRIPTION

The following disclosure provides many different examples, or examples, for implementing different features of the provided subject matter. Specific examples of components and arrangements are described below to simplify the present disclosure. These are, of course, merely examples and are not intended to be limiting. For example, the formation of a first feature over or on a second feature in the description that follows may include examples in which the first and second features are formed in direct contact, and may also include examples in which additional features may be formed between the first and second features, such that the first and second features may not be in direct contact. In addition, the present disclosure may repeat reference numerals and/or letters in the various examples. This repetition is for the purpose of simplicity and clarity and does not in itself dictate a relationship between the various examples and/or configurations discussed.

Further, spatially relative terms, such as “beneath,” “below,” “lower,” “above,” “upper” and the like, may be used herein for ease of description to describe one element or feature’s relationship to another element(s) or feature(s) as illustrated in the figures. The spatially relative terms are intended to encompass different orientations of the device in

use or operation in addition to the orientation depicted in the figures. The apparatus may be otherwise oriented (rotated 90 degrees or at other orientations) and the spatially relative descriptors used herein may likewise be interpreted accordingly.

Aspects of the disclosure provide a semiconductor device with a polling module in a control circuit for power saving. The control circuit can operate based on a clock signal and a gated clock signal. The gated clock signal is provided by a clock gating circuit based on the clock signal. Transitions of the clock signal are output in the gated clock signal in response to a clock enable signal having an enable value and transitions in the clock signal are disabled from being output in the gated clock signal in response to the clock enable signal having a disable value. The control circuit includes a first portion that is referred to as the polling module, and the polling module operates based on the clock signal. The control circuit also includes a second portion that operates based on the gated clock signal. In some examples, the second portion can have a much larger number of transistors than the first portion. In an example, the second portion is implemented using sequential circuitry that operates in response to transitions in the gated clock signal. The polling module sets the clock enable signal to the disable value in response to a disable control from the second portion and sets the clock enable signal to the enable value in response to a wakeup control that comes from for example, an external source of the control circuit. The second portion of the control circuit operates based on the gated clock signal. Thus, when the clock enable signal has the disable value, the gated clock signal has no signal transition (e.g., having a constant low voltage corresponding to "0", having a constant high voltage corresponding to "1" and the like), transistors in the second portion of the control circuits do not switch, dynamic power consumption is reduced and power saving can be achieved.

FIG. 1 shows a block diagram of a semiconductor device **100** according to some examples of the disclosure. The semiconductor device **100** includes a control circuit **130** with a polling module for power saving. In the FIG. 1 example, the control circuit **130** includes a first portion **131** that operates based on a regular clock signal CK, and a second portion **132** that operates based on a gated clock signal CK-G. The first portion **131** is also referred to as the polling module (PM) **131**.

The regular clock signal CK can be provided by a clock source **101**. In an example, the regular clock signal CK continuously oscillates between a high voltage and a low voltage when the semiconductor device **100** is powered up. In an example, the clock source **101** includes a clock generation circuit that generates the regular clock signal CK when the semiconductor device **100** is powered up. In another example, the clock source **101** receives a system clock (not shown) from an external source of the semiconductor device **100**, and provides the regular clock signal CK based on the system clock.

In some examples, the semiconductor device **100** includes a clock gating circuit **135** that is configured to generate the gated clock signal CK-G based on the regular clock signal CK and a clock enable signal EN. Transitions (e.g., voltage transitions between the high voltage and the low voltage) in the regular clock signal CK are enabled/disabled for outputting in the gated clock signal CK-G based on the clock enable signal EN. For example, when the clock enable signal EN has a first value (also referred to as enable value), such as "1" (e.g., high voltage level) in the FIG. 1 example, the clock gating circuit **135** outputs transitions (voltage transi-

tions) in the gated clock signal CK-G in response to the transitions in the regular clock signal CK; when the clock enable signal EN has a second value (also referred to as disable value), such as "0" (e.g., ground voltage level) in FIG. 1 example, the clock gating circuit **135** outputs a constant voltage level, such as ground voltage level, as the gated clock signal CK-G regardless of the transitions in the regular clock signal CK.

According to an aspect of the disclosure, the clock enable signal EN is provided by the polling module **131**. The polling module **131** operates based on the regular clock signal CK, and can include any suitable combinational circuit and sequential circuit (e.g., latches, flip-flops and the like). In some examples, the polling module **131** receives control signals from the second portion **132** and/or external sources of the control circuit **130**. For example, the polling module **131** receives a disable control from the second portion **132** and a wakeup control from one or more external sources of the control circuit **130**. The disable control can cause the polling module **131** to set the clock enable signal EN to the disable value, and the wakeup control can cause the polling module **131** to set the clock enable signal EN to the enable value.

In some examples, the second portion **132** includes a large number of transistors in sequential circuitry that operate in response to transitions in the gated clock signal CK-G. When the gated clock signal CK-G has a constant voltage level (transitions are gated), the transistors in the sequential circuitry do not switch.

During operation, in an example, initially the polling module **131** outputs the clock enable signal EN with the enable value. When the clock enable signal EN has the enable value, the clock gating circuit **135** outputs transitions in the gated clock signal CK-G in response to the transitions in the regular clock signal CK. The gated clock signal CK-G is provided to the second portion **132**, and transistors in the second portion **132** may switch in response to the gated clock signal CK-G.

In response to certain conditions (e.g., idle mode, sleep mode), the second portion **132** provides the disable control to cause the polling module **131** to output the clock enable signal EN with the disable value. When the clock enable signal EN has the disable value, the clock gating circuit **135** outputs the gated clock signal CK-G with a constant voltage level. Then, the transistors in the second portion **132** do not switch, and thus dynamic power consumption can be reduced, and power saving can be achieved.

It is noted that the polling module **131** operates based on the regular clock signal CK, and can continue operations when the second portion **132** halts operations. When the external source provides the wakeup control, the polling module **131** can output the clock enable signal EN with the enable value, and then the clock gating circuit **135** outputs transitions in the gated clock signal CK-G in response to the transitions in the regular clock signal CK. Then, the sequential circuitry in the second portion **132** can continue operations.

It is noted that semiconductor device **100** can be any suitable device. In some examples, the semiconductor device **100** is a semiconductor memory device that is described in detail with reference to FIG. 2 and FIG. 3.

FIG. 2 shows a block diagram of a semiconductor memory device **200** according to some examples of the disclosure. The semiconductor memory device **200** includes a memory cell array **202** and peripheral circuitry **201** coupled together. In some examples, the memory cell array **202** and the peripheral circuitry **201** are disposed on a same

die (chip). In other examples, the memory cell array **202** is disposed on an array die, and the peripheral circuitry **201** is disposed on a different die, such as a die that is implemented using complementary metal-oxide-semiconductor (CMOS) technology and is referred to as CMOS die. The array die and the CMOS die are suitably bonded, and electrically coupled together. An example of bonded array die and CMOS die will be described with reference to FIG. 3.

In some examples, a CMOS die can be coupled with multiple array dies. In an example, the semiconductor memory device **200** is an integrated circuit (IC) package that encapsulates one or more array dies and one or more CMOS dies.

The semiconductor memory device **200** is configured to store data in the memory cell array **202**, and perform operations in response to received commands (CMD). In some examples, the semiconductor memory device **200** can receive a write command (also referred to as program command in some examples), a read command, an erase command and the like, and operate accordingly. In an example, the semiconductor memory device **200** receives a write command with an address (ADDR) and data (DATA), the semiconductor memory device **200** then stores the data in the memory cell array **202** at the address. In another example, the semiconductor memory device **200** receives a read command with an address, the semiconductor memory device **200** then accesses the memory cell array **202**, and outputs data stored at the address of the memory cell array **202**. In another example, the semiconductor memory device **200** receives an erase command with an address, the semiconductor memory device **200** then resets one or more blocks of memory cells at the address to an un-programmed state (also referred to as erased state), such as "1" in 1-bit, "11" in 2-bit, "111" in 3-bit, and the like in the NAND flash memory technology.

Generally, the memory cell array **202** can include one or more memory planes **260**, and each of the memory planes **260** can include a plurality of memory blocks, such as block-1 to block-N as shown in FIG. 2 (N is a positive integer). In some examples, concurrent operations can take place at different memory planes **260**. In some examples, each of the memory blocks block-1 to block-N is the smallest unit to carry out an erase operation. Each memory block includes a number of pages. In some examples, a page is the smallest unit that can be programmed. In an example, memory cells of a page can share a word line.

In some examples, the memory cell array **202** is a flash memory array, and is implemented using 3D NAND flash memory technology. Each of the memory blocks block-1 to block-N includes a plurality of memory cell strings that are disposed vertically (e.g., perpendicular to a main surface of a die). Each memory cell string includes a plurality of transistors connected in series. The details of a memory cell string will be described with reference to FIG. 3.

In some examples, the peripheral circuitry **201** includes an interface circuitry **210** and a controller **220** coupled together.

The interface circuitry **210** includes suitable circuitry to interface with the memory cell array **202** or to interface with external components of the semiconductor memory device **200**, such as a host device. In some examples, the interface circuitry **210** includes a first portion that interfaces with a host device and is referred to as a host interface, and a second portion that interfaces with the memory cell array **202** and is referred to as an array interface. In the FIG. 2 example, the interface circuitry **210** includes a command decoding circuit **214**, an address decoding circuit **215**, a

page buffer circuit **212**, a data input/output (I/O) circuit **211**, and a voltage generator **213** coupled together as shown in FIG. 2.

In some examples, the address decoding circuit **215** can receive address (ADDR) from I/O pins coupled to external circuitry (e.g., the host device) and perform decoding of the address. In some examples, the address decoding circuit **215** can operate with the controller **220** to perform decoding of the address. In some examples, the received addresses from the host device are file system logical block addresses. In some examples, the address decoding circuit **215** and the controller **220** can perform functions of a flash translation layer (FTL) to translate from block addresses used by a file system to addresses of physical cells in the memory cell array **202**. In an example, the translation from block addresses used by the file system to physical cells in the memory cell array **202** can be used to exclude bad memory cells. In some examples, the addresses of the physical cells are in the form of row address (R-ADDR) and column address (C-ADDR). In response to the row address, the address decoding circuit **215** can generate the word line (WL) signals and select signals, such as top select gate (TSG) signal(s), bottom select gate (BSG) signal(s), and the like, and can provide the memory cell array **202** with the WL signals, and select signals. In some examples, during a write operation, the address decoding circuit **215** provides the WL signals and the select signals to the memory cell array **202** to select a page to program. During a read operation, the address decoding circuit **215** can provide the WL signals and the select signals to select a page for buffering. During an erase operation, the address decoding circuit **215** can provide suitable WL signals and select signals.

The page buffer circuit **212** is coupled to bit lines (BL) of the memory cell array **202** and is configured to buffer data, such as one or more pages of data during read and write operations. In an example, during a write operation, the page buffer circuit **212** can buffer data to be programmed and drive the data to bit lines of the memory cell array **202** to write the data into the memory cell array **202**. In another example, during a read operation, the page buffer circuit **212** can sense data on the bit lines of the memory cell array **202** and buffer the sensed data for outputting.

In the FIG. 2 example, the data I/O circuit **211** is coupled to the page buffer circuit **212** via data lines (DL). In an example (e.g., during a write operation), the data I/O circuit **211** is configured to receive data from external circuitry (e.g., the host device) of the semiconductor memory device **200**, and provide the received data to the memory cell array **202** via the page buffer circuit **212**. In another example (e.g., during a read operation), the data I/O circuit **211** is configured to output the data from the memory cell array **202** to external circuitry (e.g., host device) based on the column address (C-ADDR).

The voltage generator **213** is configured to generate voltages of suitable levels for the proper operations of the semiconductor memory device **200**. For example, during a read operation, the voltage generator **213** can generate voltages of suitable levels for source voltages, body voltage, various WL voltages, select voltages, and like for the read operation. In some examples, the source voltages are provided as array common source (ACS) voltages to the source terminals of the memory cell array **202** during the read operation; the body voltage is provided to, for example a P-type well (PW) that is the body portion for the memory cell strings, during the read operation. The WL voltages and the select voltages are provided to the address decoding circuit **215**, thus the address decoding circuit **215** can output

the WL signals and the select signals (e.g. TSG signals and BSG signals) at the suitable voltage levels during the read operation.

In another example, during an erase operation, the voltage generator **213** can generate voltages of suitable levels for source voltages, body voltage, various WL voltages, select voltages, BL voltages and like that are suitable for the erase operation. In some examples, the source voltage is provided as ACS voltages to the source terminals of the memory cell array **202** during the erase operation; the PW voltage is provided to the P-type well that is the body portion for the memory cell strings during the erase operation. The WL voltages and the select voltages are provided to the address decoding circuit **215**, thus the address decoding circuit **215** can output the WL signals and the BSG and TSG signals at the suitable voltage levels during the erase operation. The BL voltages are provided to the page buffer circuit **212**, thus the page buffer circuit **212** can drive the bit lines (BL) at proper voltage levels during the erase operation. It is noted that the BL voltages may be applied to the bit lines without going through the page buffer circuit **212** in some examples.

In another example, during a write operation, the voltage generator **213** can generate voltages of suitable levels for source voltages, body voltage, various WL voltages, select voltages, BL voltages, verification voltages, reference voltages and like that are suitable for the write operation. In some examples, the source voltage is provided as ACS voltages to the source terminals of the memory cell array **202** during the write operation; the PW voltage is provided to the P-type well that is the body portion for the memory cell strings during the write operation. The WL voltages, the select voltages, and verification voltages are provided to the address decoding circuit **215**, thus the address decoding circuit **215** can output the WL signals and the BSG and TSG signals at the suitable voltage levels during the write operation. The BL voltages and the reference voltages are provided to the page buffer circuit **212**, thus the page buffer circuit **212** can drive the bit lines (BL) at proper voltage levels during the write operation, and can sense programming status in the verification steps during the write operation.

In some examples, the command decoding circuit **214** is configured to receive commands (CMD) from, for example the host device via I/O pins in command cycles. In some examples, the I/O pins can transmit other information, such as addresses in address cycles, data in data cycles. In some examples, the received commands are commands according to certain high level protocols (e.g., USB protocols).

In some examples, the command decoding circuit **214** and the controller **220** can operate together to decode the received commands. In an example, the command decoding circuit **214** performs initial decoding of the received commands and the commands decoded by the command decoding circuit **214** are provided to the controller **220** for further processing. The controller **220** can perform further decoding, and then generate control parameters for controlling other circuits, such as the page buffer circuit **212**, the data I/O circuit **211**, the voltage generator **213**, and the like based on the commands.

In some examples, the controller **220** can control the voltage generator **213** to generate voltages of suitable levels based on the commands. The controller **220** can coordinate the other circuits, to provide signals to the memory cell array **202** at the suitable time and suitable voltage levels.

In the FIG. 2 example, the controller **220** is implemented with polling modules in a similar manner as the control circuit **130** in FIG. 1 for power saving. In the FIG. 2

example, the controller **220** includes multiple processing cores that can cooperate during operations. In some examples, while the multiple processing cores can operate simultaneously, in some scenarios, some processing cores may need to wait for feedback signals from other processing cores or new commands from the host device before further processing operations. According to some aspects of the present disclosure, in such scenarios when a processing core detects an idle state (e.g., waiting for feedback signals from other processing cores or new commands from the host device), the processing core can provide a disable control to a polling module that is coupled with the processing core, and the polling module can provide a clock enable signal with a disable value to cause a clock gating circuit to output a gated clock signal with a constant voltage. The gated clock signal is provided to the processing core, and the processing core can stop signal switching due to the constant voltage of the gated clock signal.

In some examples, the controller **220** includes multiple microcontroller units (MCUs), such as shown by MCU-1 **230**, MCU-P **250** (P is a positive integer) and the like. Each MCU includes a polling module (PM), one or more processing cores (PCs), a clock gating circuit (CGC), and some memories, such as read-only memory (ROM), random access memory (RAM) and the like. The polling module is also referred to as a first portion of the MCU and the one or more processing cores can be referred to as a second portion of the MCU. For example, the MCU-1 **230** includes a PC-1 **232**, a PM-1 **231**, a CGC-1 **235**, a ROM-1 **237**, and a RAM-1 **238**; and the MCU-P **250** includes a PC-P **252**, a PM-P **251**, a CGC-P **255**, a ROM-P **257**, and a RAM-P **258**. It is noted that the controller **220** can include other MCUs (not shown) that are similarly configured as the MCU-1 **230** and the MCU-P **250**.

In the following description, MCU-1 **230** is described in detail as an example. The description can be suitably applied to other MCUs, such as the MCU-P **250**, and the like.

In the FIG. 2 example, the PM-1 **231** operates based on a regular clock signal CK, and a PC-1 **232** operates based on a gated clock signal CK-G-1. The regular clock signal CK can be provided by a clock source (not shown). In an example, the regular clock signal CK continuously oscillates between a high voltage and a low voltage when the semiconductor memory device **200** is powered up. In an example, the clock source includes a clock generation circuit that generates the regular clock signal CK when the semiconductor memory device **200** is powered up. In another example, the clock source receives a system clock from an external source of the semiconductor memory device **200** via an I/O pin (not shown) of the semiconductor memory device **200**, and generates the regular clock signal CK based on the system clock.

In some examples, the CGC-1 **235** can generate the gated clock signal CK-G-1 based on the regular clock signal CK and a clock enable signal EN-1. Transitions (e.g., voltage transitions between a high voltage and a low voltage) in the regular clock signal CK are enabled/disabled for outputting in the gated clock signal CK-G-1 based on the clock enable signal EN-1. For example, when the clock enable signal EN-1 has a first value (also referred to as enable value), such as "1" (e.g., high voltage level), the CGC-1 **235** outputs transitions (voltage transitions) in the gated clock signal CK-G-1 in response to the transitions in the regular clock signal CK; when the clock enable signal EN-1 has a second value (also referred to as disable value), such as "0" (e.g., ground voltage level), the CGC-1 **235** outputs a constant

voltage level, such as ground voltage level, as the gated clock signal CK-G-1 regardless of the transitions in the regular clock signal CK.

According to an aspect of the disclosure, the clock enable signal EN-1 is provided by the PM-1 231. The PM-1 231 operates based on the regular clock signal CK, and can include any suitable combinational circuit and sequential circuit (e.g., latches, flip-flops and the like). In some examples, the PM-1 231 receives a disable control DC-1 from the PC-1 232 and a wakeup control WC-1 from an external source of the MCU-1 230. The disable control DC-1 can cause the PM-1 231 to set the clock enable signal EN-1 to the disable value, and the wakeup control WC-1 can cause the PM-1 231 to set the clock enable signal EN-1 to the enable value.

Generally, the PC-1 232 is implemented using sequential circuitry, for example, using pipeline architecture. Transistors in the PC-1 232, such as transistors in flip-flops and the like, can switch in response to transitions in the CK-G-1, such as rising edges of the CK-G-1, falling edges of the CK-G-1. When the CK-G-1 is gated (e.g., transitions are disabled), the CK-G-1 has a constant voltage level, such as ground voltage level, and the transistors in the PC-1 232 may halt switching. Thus, dynamic power consumption can be reduced, and power saving can be achieved.

In some examples, the PC-1 232 is suitably coupled with the ROM-1 237 and the RAM-1 238 and can access the ROM-1 237 and the RAM-1 238 during operation. For example, the ROM-1 237 stores firmware instructions, and the PC-1 232 can access the ROM-1 237 to read the firmware instructions and execute the firmware instructions. Further, the PC-1 232 can access the RAM-1 238 to store data and to read the stored data during operation in some examples.

According to an aspect of the disclosure, the PC-1 232 can execute firmware to generate the disable control DC-1. In some examples, initially the PM-1 231 outputs the clock enable signal EN-1 with the enable value. When the clock enable signal EN-1 has the enable value, the CGC-1 235 outputs transitions in the gated clock signal CK-G-1 in response to the transitions in the regular clock signal CK. The gated clock signal CK-G-1 is provided to the PC-1 232, and transistors in the PC-1 232 can switch in response to the gated clock signal CK-G-1. For example, in response to the gated clock signal CK-G-1, the PC-1 232 can execute firmware instructions that set a value in a register (not shown). For ease of description, the register is referred to as MCU-disable register and is an internal register of the MCU-1 230. In some examples, the MCU-disable register is in the PM-1 231. In an example, the PC-1 232 can execute firmware instructions to set the MCU-disable register to "1". Further, in response to a switch from "0" to "1" in the MCU-disable register, the PM-1 231 can output the EN-1 with the disable value.

When the clock enable signal EN-1 has the disable value, the CGC-1 235 outputs the gated clock signal CK-G-1 with a constant voltage level, such as ground voltage level. Then, transistors, such as transistors in flip-flops, in the PC-1 232 do not switch, and thus dynamic power consumption can be reduced, and power saving can be achieved.

It is noted that the PM-1 231 operates based on the regular clock signal CK, and can continue operations when the PC-1 232 halts operations. When an external source, such as the MCU-P 250, host device, and the like provides a signal in the wakeup control WC-1, for example, a signal switching from "0" to "1" from the wakeup source, the MCU-disable register can be cleared and can have a value "0". In response

to the MCU-disable register having the value "0", the PM-1 231 outputs the clock enable signal EN-1 with the enable value. Thus, the CGC-1 235 outputs transitions in the gated clock signal CK-G-1 in response to transitions in the regular clock signal CK. In response to the transitions in the gated clock signal CK-G-1, the PC-1 232 can wake up and continue operations.

It is noted that the wakeup control WC-1 can include signals from multiple wake up sources. In some examples, the multiple wakeup sources can be suitably ordered according to a priority sequence, and the PM-1 231 can generate a wake up status WU-1 to indicate which wake up source triggers the current wakeup. In some examples, the wakeup status WU-1 can be used to locate portions of firmware to restore firmware execution. In some related example, without the wakeup status, the processing core needs time to determine where to continue the operation after each wakeup, and performance may be sacrificed.

According to an aspect of the disclosure, firmware based clock gating is used to control the clock gating operations in the MCUs. Firmware modules can be updated to include the firmware based clock gating, and the firmware modules can be suitably reused. Thus, the firmware based clock gating provides flexibility in implementation.

According to another aspect of the disclosure, turning off the processing cores can save a large portion of dynamic power consumption. Further, the wakeup status can be used to restore the MCU operation and to keep the continuity of the MCU operation, without sacrificing performance. The wakeup status will be further discussed with reference to FIG. 4 and FIG. 5.

FIG. 3 shows a cross-sectional view of a semiconductor memory device 300 according to some examples of the disclosure. The semiconductor memory device 300 can be the semiconductor memory device 200 in some examples. The semiconductor memory device 300 includes an array die 302 and a CMOS die 301 bonded together according to some examples of the disclosure.

It is noted that, in some examples, a semiconductor memory device can include multiple array dies and a CMOS die. The multiple array dies and the CMOS die can be stacked and bonded together. The CMOS die is respectively coupled to the multiple array dies, and can drive the respective array dies to operate in the similar manner as the semiconductor memory device 300.

The array die 302 includes a substrate 303, and memory cells formed on the substrate 303. The CMOS die 301 includes a substrate 304, and peripheral circuitry formed on the substrate 304. For simplicity, the main surface of the substrate 303 is referred to as an X-Y plane, and the direction perpendicular to the main surface is referred to as Z direction.

The substrate 303 and the substrate 304 respectively can be any suitable substrate, such as a silicon (Si) substrate, a germanium (Ge) substrate, a silicon-germanium (SiGe) substrate, and/or a silicon-on-insulator (SOI) substrate. The substrate 303 and the substrate 304 respectively may include a semiconductor material, for example, a Group IV semiconductor, a Group III-V compound semiconductor, or a Group II-VI oxide semiconductor. The Group IV semiconductor may include Si, Ge, or SiGe. The substrate 303 and the substrate 304 respectively may be a bulk wafer or an epitaxial layer.

The semiconductor memory device 300 includes memory cell arrays (e.g., the memory cell array 202) and peripheral circuitry (e.g., the address decoding circuit 215, the page buffer circuit 212, the data I/O circuit 211, the voltage

generator 213, the controller 220 and the like). In the FIG. 3 example, the memory cell arrays are formed on the substrate 303 of the array die 302 and the peripheral circuitry is formed on the substrate 304 of the CMOS die 301. The array die 302 and the CMOS die 301 are disposed face to face (the surface with circuitry disposed on is referred to as face, and the opposite surface is referred to as back), and bonded together.

In some examples, wells can be formed in the substrate 303 respectively for blocks as body portions for the blocks. In the FIG. 3 example, a P-type well 305 is formed in the substrate 303, and a block of three dimensional (3D) NAND memory cell strings can be formed in the P-type well 305. The P-type well 305 can form a body portion (e.g., in connection with a PW terminal) for the 3D NAND memory cell strings, and a voltage that is referred to as PW can be applied to the P-type well 305 via the PW terminal. In some examples, the memory cell array is formed in a core region 306 as an array of vertical memory cell strings. Besides the core region 306 and the periphery region, the array die 302 includes a staircase region 307 (also referred to as a connection region in some examples) to facilitate making connections to, for example, gates of the memory cells in the vertical memory cell strings, gates of the select transistors, and the like. The gates of the memory cells in the vertical memory cell strings correspond to word lines for the NAND memory architecture.

In the FIG. 3 example, a vertical memory cell string 380 is shown as representation of an array of vertical memory cell strings formed in the core region 306. FIG. 3 also shows a schematic symbol version of the vertical memory cell string 380' corresponding to the vertical memory cell string 380. The vertical memory cell strings 380 are formed in a stack of layers 390. The stack of layers 390 includes gate layers 395 and insulating layers 394 that are stacked alternately. The gate layers 395 and the insulating layers 394 are configured to form transistors that are stacked vertically. In some examples, the stack of transistors includes memory cells and select transistors, such as one or more bottom select transistors, one or more top select transistors and the like. In some examples, the stack of transistors can include one or more dummy select transistors. The gate layers 395 correspond to gates of the transistors. The gate layers 395 are made of gate stack materials, such as high dielectric constant (high-k) gate insulator layers, metal gate (MG) electrode, and the like. The insulating layers 394 are made of insulating material(s), such as silicon nitride, silicon dioxide, and the like.

According to some aspects of the disclosure, the vertical memory cell strings are formed of channel structures 381 that extend vertically (Z direction) into the stack of layers 390. The channel structures 381 can be disposed separate from each other in the X-Y plane. In some examples, the channel structures 381 are disposed in the form of arrays between gate line cut structures (not shown). The gate line cut structures are used to facilitate replacement of sacrificial layers with the gate layers 395 in a gate-last process. The arrays of the channel structures 381 can have any suitable array shape, such as a matrix array shape along the X direction and the Y direction, a zig-zag array shape along the X or Y direction, a beehive (e.g., hexagonal) array shape, and the like. In some examples, each of the channel structures has a circular shape in the X-Y plane, and a pillar shape in the X-Z plane and Y-Z plane. In some examples, the quantity and arrangement of the channel structures between gate line cut structures is not limited.

In some examples, the channel structure 381 has a pillar shape that extends in the Z direction that is perpendicular to the direction of the main surface of the substrate 303. In an example, the channel structure 381 is formed by materials in the circular shape in the X-Y plane, and extends in the Z direction. For example, the channel structure 381 includes function layers, such as a blocking insulating layer 382 (e.g., silicon oxide), a charge storage layer (e.g., silicon nitride) 383, a tunneling insulating layer 384 (e.g., silicon oxide), a semiconductor layer 385, and an insulating layer 386 that have the circular shape in the X-Y plane, and extend in the Z direction. In an example, the blocking insulating layer 382 (e.g., silicon oxide) is formed on the sidewall of a hole (into the stack of layers 390) for the channel structure 381, and then the charge storage layer (e.g., silicon nitride) 383, the tunneling insulating layer 384, the semiconductor layer 385, and the insulating layer 386 are sequentially stacked from the sidewall. The semiconductor layer 385 can be any suitable semiconductor material, such as polysilicon or monocrystalline silicon, and the semiconductor material may be un-doped or may include a p-type or n-type dopant. In some examples, the semiconductor material is intrinsic silicon material that is un-doped. However due to defects, intrinsic silicon material can have a carrier density in the order of 10^{10} cm^{-3} in some examples. The insulating layer 386 is formed of an insulating material, such as silicon oxide and/or silicon nitride, and/or may be formed as an air gap.

According to some aspects of the disclosure, the channel structure 381 and the stack of layers 390 together form the memory cell string 380. For example, the semiconductor layer 385 corresponds to the channel portions for transistors in the memory cell string 380, and the gate layers 395 correspond to the gates of the transistors in the memory cells string 380. Generally, a transistor has a gate that controls a channel, and has a drain and a source at each side of the channel. For simplicity, in the FIG. 3 example, the upper side of the channel for transistors in FIG. 3 is referred to as the drain, and the bottom side of the channel for transistors in FIG. 3 is referred to as the source. It is noted that the drain and the source can be switched under certain driving configurations. In the FIG. 3 example, the semiconductor layer 385 corresponds to connected channels of the transistors. For a specific transistor, the drain of the specific transistor is connected with a source of an upper transistor above the specific transistor, and the source of the specific transistor is connected with a drain of lower transistor below the specific transistor. Thus, the transistors in the memory cell string 380 are connected in series.

The memory cell string 380 includes memory cell transistors (or referred to as memory cells). A memory cell transistor can have different threshold voltages based on carrier trappings in a portion of the charge storage layer 383 that corresponds to a floating gate for the memory cell transistor. For example, when a significant amount of holes are trapped (stored) in the floating gate of the memory cell transistor, the threshold voltage of the memory cell transistor is lower than a predefined value, then the memory cell transistor is in a un-programmed state (also referred to as erased state) corresponding to logic "11" in two binary bits. When holes are expelled from the floating gate (or electrons are trapped in the floating gate), the threshold voltage of the memory cell transistor is increased, thus the memory cell transistor can be programmed to other suitable states.

The memory cell string 380 includes one or more top select transistors configured to couple/de-couple the memory cells in the memory cell string 380 to a bit line, and

includes one or more bottom select transistors configured to couple/de-couple the memory cells in the memory cell string **380** to the ACS.

The top select transistors are controlled by top select gates (TSG). For example, when a TSG voltage (voltage applied to the TSG) is larger than a threshold voltage of the top select transistors, the top select transistors are turned on and the memory cells are coupled to the bit line; and when the TSG voltage (voltage applied to the TSG) is smaller than the threshold voltage of the top select transistors, the top select transistors are turned off and the memory cells are de-coupled from the bit line.

Similarly, the bottom select transistors are controlled by bottom select gates (BSG). For example, when a BSG voltage (voltage applied to the BSG) is larger than a threshold voltage of the bottom select transistors, the bottom select transistors are turned on and the memory cells are coupled to the ACS; and when the BSG voltage (voltage applied to the BSG) is smaller than the threshold voltage of the bottom select transistors, the bottom select transistors are turned off and the memory cells are de-coupled from the ACS.

According to some aspects of the disclosure, the bottom portion of the semiconductor layer **385** in the channel hole corresponds to a source side of the vertical memory cell string **380**, and the bottom portion is labeled as **385(S)**. A common source layer **389** is formed in conductive connection with the source of the vertical memory cell string **380**. The common source layer **389** can include one or more layers. In some examples, the common source layer **389** includes a silicon material, such as intrinsic polysilicon, doped polysilicon (such as N-type doped silicon, P-type doped silicon) and the like. In some examples, the common source layer **389** may include metal silicide to improve conductivity. The common source layer **389** is similarly in conductive connection with sources of other vertical memory cell strings (not shown), and thus forms an array common source (ACS).

In some examples, when the vertical memory cell strings **380** are configured to be erased by blocks, the common source layer **389** can extend and cover the core regions of a block and staircase regions for the block. In some examples, for different blocks that are erased separately, the common source layer **389** may be suitably insulated for the different blocks.

In the FIG. 3 example, in the channel structure **381**, the semiconductor layer **385** extends vertically from the source side of the channel structure **381** up, and forms a top portion corresponding to a drain side of the vertical memory cell string **380**. The top portion of the semiconductor layer **385** is labeled as **385(D)**. It is noted that drain side and the source side are named for the ease of description. The drain side and the source side may function differently from the names.

In the FIG. 3 example, a connection structure, such as a via structure **372** with a metal wire **373**, a bonding structure **374**, and the like, can be formed to electrically couple the top portion of the semiconductor layer **385(D)** with a bit line (BL).

Further in the FIG. 3 example, the staircase region **307** includes a staircase that is formed to facilitate word line connections to the gates of transistors (e.g., memory cells, top select transistor(s), bottom select transistor(s)). For example, a word line connection structure **370** includes a contact structure **371**, a via structure **372**, and a metal wire **373** that are conductively coupled together. The word line connection structure **370** can electrically couple a WL to a gate terminal of a transistor in the memory cell string **380**.

In the FIG. 3 example, the array die **302** and the CMOS die **301** are disposed face-to-face (circuitry side is face, and the substrate side is back) and bonded together. Generally, the peripheral circuitry on the CMOS die interfaces the semiconductor memory device **300** with external circuitry.

In the FIG. 3 example, the CMOS die **301** and the array die **302** respectively include bonding structures that can be aligned with each other. For example the CMOS die **301** includes a bonding structure **334** and the array die **302** includes a corresponding bonding structure **374**. The array die **302** and the CMOS die **301** can be suitably aligned, thus the bonding structure **334** is aligned with the bonding structure **374**. When the array die **302** and the CMOS die **301** are bonded together, the bonding structure **334** is respectively bonded and electrically coupled with the bonding structure **374**.

While a 3D NAND flash memory device is described in detail with reference to FIG. 2 and FIG. 3, some aspects of the present disclosure are not limited to a 3D NAND flash memory device.

As described with reference to FIG. 2, the wakeup control, such as WU-1 and the like can include signals from multiple wakeup sources. In some examples, any one of wakeup sources can cause the MCU-disable register to be cleared (e.g., to be "0"), and to restore the transitions in the gated clock signal. In some examples, wakeup signal information, such as priority, and the like can be suitably recorded, and a wakeup status can be generated accordingly. The wakeup status can be used to achieve operation continuity.

In some examples, more than one wakeup source may have wakeup conditions at the same time, the wakeup status can be generated to indicate the wakeup source with the highest priority. In an example, a polling module, such as the polling module PM-1 **231**, and the like, includes a first-in-first-out (FIFO) queue that can queue information of wakeup sources (have wakeup conditions) according to a priority sequence. For example, the queue can store wakeup statuses respectively associated with wakeup sources according to the priority sequence of the wakeup sources.

FIG. 4 shows a table **400** of wakeup source priorities according to some examples of the disclosure. For each operation type (e.g., read operation type, program operation type, erase operation type), multiple wakeup conditions can be defined. For example, a read operation type can include a first wakeup condition from read wakeup source **0**, a second wakeup condition from read wakeup source **1**, and a third wakeup condition from read wakeup source **2**. The wakeup conditions have a priority sequence of the read wakeup source **0** (highest priority), the read wakeup source **1** and the read wakeup source **3** (lowest priority). When multiple wakeup conditions happen at the same time, for example, the first wakeup condition from the read wakeup source **0** and the third wakeup condition from the read wakeup source **2** happen in a same clock cycle, the wakeup signal information can be suitably stored. For example, a first wakeup status indicative of the read wakeup source **0** and a second wakeup status indicative of the read wakeup source **2** can be stored for example in a queue. Then, first operations (first firmware portion) associated with the first wakeup status can be performed and then second operations (second firmware portion) associated with the second wakeup status can be performed.

According to an aspect of the disclosure, MCU clock gating functions can be selectively disabled for respective operation types (e.g., read operation type, program operation type, erase operation type). In some examples, the semicon-

ductor memory device **200** is tested at a factory before being sold to a client. During the test, the factory may determine to disable MCU clock gating functions for one or more operation types due to, for example, performance issues in a corner case, the factory can store three factory setup parameters (referred to as `mcu_cg_dis_read`, `mcu_cg_dis_pgm`, `mcu_cg_dis_ers`) in, for example, an initialization partition **265** in the memory cell array **202**. In an example, the factory setup parameter `mcu_cg_dis_read` is used to indicate whether to disable clock gating function for read operation type (e.g., “1” for disable); the factory setup parameter `mcu_cg_dis_pgm` is used to indicate whether to disable clock gating function for program operation type (e.g., “1” for disable); and the factory setup parameter `mcu_cg_dis_ers` is used to indicate whether to disable clock gating function for erase operation type (e.g., “1” for disable).

The information in the initialization partition **265** can be loaded in the controller **220** (e.g., RAM-1 **238**, RAM-P **258** and the like) when the semiconductor memory device **200** is powered up. Based on the three factory setup parameters `mcu_cg_dis_read`, `mcu_cg_dis_pgm`, `mcu_cg_dis_ers`, clock gating functions can be disabled for one or more operation types. In an example, the factory setup parameter `mcu_cg_dis_read` has a value of “1” (disable clock gating function for read operation type), the factory setup parameter `mcu_cg_dis_pgm` has a value of “0”, `mcu_cg_dis_ers` has a value of “0”. Then, clock gating function can be disabled for read operation type, and clock gating functions can be performed during the program operations and the erase operations. For read operations, even though the MCU-disable register has a value “1” (indicative of clock gating), the clock enable signal (e.g., EN-1, EN-P and the like) is kept at value “1” (transitions are not gated). It is noted that, in this example, for program operations and erase operations, the clock enable signal (e.g., EN-1, EN-P and the like) can be value “0” (transitions are gated) when the MCU-disable register has a value “1” (indicative of clock gating).

FIG. 5 shows a plot **500** for illustrating signals in a control circuit according to an example of the disclosure. For example, the control circuit is the MCU-1 **230** in FIG. 2. The plot includes a status chart **510** for the operation status of PC-1 **232**; a waveform **520** for the clock enable signal EN-1; a waveform **530** for the regular clock signal CK; a waveform **540** for the gated clock signal CK-G-1; a waveform **550** for a signal from a wakeup source **0**; a waveform **560** for a signal from a wakeup source **1**; and a waveform **570** for the wakeup status.

In an example, initially, as shown by **511** in the status chart **510**, the PC-1 **232** executes firmware portion **1** (FW-P1) during an operation, such as a read operation, a program operation, an erase operation and the like. At certain point, such as shown by **512**, the PC-1 **232** waits for signals from other MCUs or a host device, and the firmware portion **1** can cause the PC-1 **232** to set the value in the MCU-disable register to “1”.

In response to the MCU-disable register having the value “1”, the PM-1 **231** can generate the clock enable signal EN-1 with the disable value “0” as shown by **522**.

In response to the clock enable signal EN-1 with the disable value “0”, the CGC-1 **235** can output a constant voltage level (e.g., ground) in the gated clock signal CK-G-1, as shown by **542**, regardless of the transitions in the regular clock signal CK. When the gated clock signal

CK-G-1 has no signal transitions, the PC-1 **232** is in the idle state with reduced dynamic power consumption for power saving, as shown by **513**.

In the FIG. 5 example, the WC-1 includes a signal from the wakeup source **0** as shown by **550** and a signal from the wakeup source **1** as shown by **560**. When the signal from the wakeup source **0** has a pulse as shown by **554**, the PM-1 **231** can clear the MCU-disable register (e.g., thus MCU disable register has the value “0”) and outputs a wakeup status as shown by **574**. In response to the MCU-disable register having the value “0”, the PM-1 **231** can generate the clock enable signal EN-1 with the enable value “1” as shown by **524**.

In response to the clock enable signal EN-1 with the enable value “1”, the CGC-1 **235** can output transitions in the gated clock signal CK-G-1 in response to transitions in the regular clock signal CK as shown by **544**. In response to the transitions in the gated clock signal CK-G-1, the PC-1 **232** continues operation, for example executes firmware portion **2** (FW-P2) as shown by **515**. In an example, the firmware portion **2** (FW-P2) is associated with the wakeup status being “01” in binary.

Further, at a certain point, such as shown by **516** while the PC-1 **232** executes firmware portion **2** (FW-P2), the PC-1 waits for signals from other MCUs or a host device, and the firmware portion **2** can cause the PC-1 **232** to set the value in the MCU-disable register to “1”.

In response to the MCU-disable register having the value “1”, the PM-1 **231** can generate the clock enable signal EN-1 with the disable value “0” as shown by **526**.

In response to the clock enable signal EN-1 having the disable value “0”, the CGC-1 **235** can output a constant voltage level (e.g., ground voltage level) in the gated clock signal CK-G-1 regardless of the transitions in the regular clock signal CK as shown by **546**. When the gated clock signal CK-G-1 has no signal transitions, the PC-1 **232** is in the idle state with reduced dynamic power consumption for power saving, as shown by **517**.

In the FIG. 5 example, when the signal from wakeup source **1** has a pulse as shown by **568**, the PM-1 **231** can clear the MCU-disable register (e.g., then MCU disable register has the value “0”) and outputs a wakeup status as shown by **578**. In response to the MCU-disable register having the value “0”, the PM-1 **231** can generate the clock enable signal EN-1 with the enable value “1” as shown by **528**.

In response to the clock enable signal EN-1 with the enable value “1”, the CGC-1 **235** can output transitions in the gated clock signal CK-G-1 in response to transitions in the regular clock signal CK as shown by **548**. In response to the transitions in the gated clock signal CK-G-1, the PC-1 **232** continues operation, for example executes firmware portion **3** (FW-P3) as shown by **519**. In an example, the firmware portion **3** (FW-P3) is associated with the wakeup status being “10” in binary.

In some related examples, when a processing core wakes up, the processing core spends some processing time to determine a portion of firmware to continue operation. Comparing to the related examples, the PC-1 **232** can directly execute a portion of firmware associated with the wakeup status without consuming additional processing time to keep the continuity of the operation.

Further, according to an aspect of the disclosure, using firmware based clock gating control, existing firmware can be flexibly upgraded and firmware modules can be reused.

FIG. 6 shows a change from a first firmware control flow 600A to a second firmware control flow 600B according to some examples of the disclosure.

The first firmware control flow 600A can be an existing firmware flow used for a firmware with multiple portions.

At S610A, a first portion of the firmware is executed for example by a processing core.

At S620A, the processing core waits for a feedback signal.

At S630A, a second portion of the firmware is executed in response to the feedback signal.

The first firmware control flow 600A can be changed to add clock disable judgement for firmware based clock gating control, such as shown by the second firmware control flow 600B. The second firmware control flow 600B can be used in the semiconductor memory device 200.

At S610B, a first portion of the firmware is executed for example, by the processing core PC-1 232.

At S620B, a wakeup status queue can be checked to determine whether to disable transitions in a clock. When the wakeup status queue is empty, the second firmware control flow proceeds to S625B; when the wakeup status queue is not empty, the second firmware control flow proceeds to S630B.

At S625B, the MCU-disable register is set to value "1". When the MCU-disable register has value "1", the polling module PM-1 231 outputs the clock enable signal EN-1 with the disable value (e.g., "0"). Then, the clock gating circuit CGC-1 235 outputs a constant voltage (e.g., ground voltage level) in the gated clock signal CK-G-1 regardless of transitions in the regular clock signal CK.

When a wakeup source provides a signal for example having a pulse, the polling module PM-1 231 clears the MCU-disable register (e.g., to have value "0"), and outputs the clock enable signal EN-1 with the enable value (e.g., "1"). The polling module PM-1 231 also queues a wakeup status indicative of the wakeup source in the wakeup status queue.

At S630B, a wakeup status is obtained from the wakeup status queue, and a second portion of the firmware associated with the wakeup status is executed.

FIG. 7 shows a flow chart outlining a process 700 according to some examples of the disclosure. In some examples, the process 700 is executed in a semiconductor device, such as by the first portion 131 of the control circuit 130 in the semiconductor device 100, by the PM-1 231 of the MCU-1 230 in the semiconductor memory device 200, and the like for power saving. The process 700 starts at S701 and proceeds to S710.

At S710, a disable control is received. Using the PM-1 231 in the FIG. 2 as an example, the PM-1 231 receives the disable control DC-1 from the PC-1 232. In some examples, the PC-1 232 executes first instructions that generate the disable control. For example, the PC-1 232 executes first instructions and expects an idle state, for example to wait for feedback signals other MCUs, or input from host device. In response to the expected idle state, the PC-1 232 provides the disable control to the PM-1 231.

At S720, in response to the disable control, signal transitions in a gated clock signal are disabled. For example, in response to the DC-1, the PM-1 231 disables signal transitions in the CK-G-1. The CK-G-1 is used by the PC-1 232. In some examples, the PM-1 231 includes a storage element, such as a register (MCU-disable register) and the like. The storage element can be set to a first state in response to the disable control. Then, a clock enable signal (e.g., EN-1) of

a clock gating circuit (e.g., CGC-1 235) can be set according to the stored state in the storage element.

It is noted that, in some examples, when the semiconductor device or semiconductor memory device includes factory setup parameters (e.g., mcu_cg_dis_read, mcu_cg_dis_pgm, mcu_cg_dis_ers and the like) to disable clock gating functions, the polling module can set the clock enable signal to the enable value based on the factory setup parameters regardless of the disable control.

At S730, in response to a wakeup control, the PM-1 231 enables the signal transitions in the CK-G-1. In an example, the storage element is cleared to have a second state in response to the wakeup control. Then, a clock enable signal (e.g., EN-1) of a clock gating circuit (e.g., CGC-1 235) is set according to the stored state in the storage element. In some examples, the wakeup control includes signals from a plurality of wakeup sources. Then, the polling module PM-1 231 can output a wakeup status that is indicative of a wakeup source from the plurality of wakeup sources based on a priority sequence. In some examples, in responses to the signal transitions in the gated clock signal CK-G-1, the PC-1 232 can execute second instructions associated with the wakeup status.

Then, the process proceeds to S799 and terminates.

It is noted that the semiconductor memory device 200 can be suitably used in a memory system.

FIG. 8 shows a block diagram of a memory system device 800 according to some examples of the disclosure. The memory system device 800 includes one or more semiconductor memory devices, such as shown by semiconductor memory devices 811-814, that are respectively configured similarly as the semiconductor memory device 200. In some examples, the memory system device 800 is a solid state drive (SSD).

The memory system device 800 includes other suitable components. For example, the memory system device 800 includes an interface 801 and a master controller 802 coupled together as shown in FIG. 8. The memory system device 800 can include a bus 820 that couples the master controller 802 with the semiconductor memory devices 811-814. In addition, the master controller 802 is connected with the semiconductor memory devices 811-814 respectively, such as shown by respective control lines 821-824.

The interface 801 is suitably configured mechanically and electrically to connect between the memory system device 800 and a host device, and can be used to transfer data between the memory system device 800 and the host device.

The master controller 802 is configured to connect the respective semiconductor memory devices 811-814 to the interface 801 for data transfer. For example, the master controller 802 is configured to provide enable/disable signals respectively to the semiconductor memory devices 811-814 to active one or more semiconductor memory devices 811-814 for data transfer.

The master controller 802 is responsible for the completion of various instructions within the memory system device 800. For example, the master controller 802 can perform bad block management, error checking and correction, garbage collection, and the like.

In some embodiments, the master controller 802 is implemented using a processor chip. In some examples, the master controller 802 is implemented using the techniques of polling modules for power saving shown in FIG. 1. In some examples, the master controller 802 is implemented using multiple MCUs, and can be implemented using the techniques of polling module for power saving used in the controller 220.

The foregoing outlines features of several examples so that those skilled in the art may better understand the aspects of the present disclosure. Those skilled in the art should appreciate that they may readily use the present disclosure as a basis for designing or modifying other processes and structures for carrying out the same purposes and/or achieving the same advantages of the examples introduced herein. Those skilled in the art should also realize that such equivalent constructions do not depart from the spirit and scope of the present disclosure, and that they may make various changes, substitutions, and alterations herein without departing from the spirit and scope of the present disclosure.

What is claimed is:

1. A semiconductor device, comprising:
 - a clock gating circuit configured to output a gated clock signal based on a clock signal, transitions of the clock signal being enable from being output in the gated clock signal in response to a clock enable signal having an enable value and being disabled from being output in the gated clock signal in response to the clock enable signal having a disable value; and
 - a control circuit that comprises:
 - a polling module configured to operate based on the clock signal and set the clock enable signal to the disable value in response to a disable control, and set the clock enable signal to the enable value in response to a wakeup control; and
 - a processing core configured to operate based on the gated clock signal, the processing core providing the disable control to the polling module during an operation.
2. The semiconductor device of claim 1, wherein the processing core is configured to execute first instructions during the operation, and the first instructions cause the processing core to provide the disable control.
3. The semiconductor device of claim 1, wherein the polling module comprises a storage element configured to:
 - be in a first state in response to the disable control; and
 - be in a second state in response to the wakeup control.
4. The semiconductor device of claim 2, wherein the wakeup control includes signals from a plurality of wakeup sources, and the polling module is configured to output a wakeup status that is indicative of a wakeup source from the plurality of wakeup sources.
5. The semiconductor device of claim 4, wherein the polling module is configured to output the wakeup status that is indicative of the wakeup source from the plurality of wakeup sources based on a priority sequence.
6. The semiconductor device of claim 4, wherein the processing core is configured to execute second instructions associated with the wakeup status.
7. The semiconductor device of claim 1, wherein the polling module is configured to set, based on a factory setup parameter, the clock enable signal to the enable value regardless of the disable control.
8. A semiconductor memory device, comprising:
 - a memory cell array comprising a block of memory cells; and
 - peripheral circuitry coupled with the memory cell array, the peripheral circuitry comprising:
 - a microcontroller unit (MCU) comprising:
 - a clock gating circuit configured to output a gated clock signal based on a clock signal, transitions of the clock signal being enabled from being output in the gated clock signal in response to a clock enable signal having an enable value and being

- disabled from being output in the gated clock signal in response to the clock enable signal having a disable value;
 - a polling module configured to operate based on the clock signal and set the clock enable signal to the disable value in response to a disable control, and set the clock enable signal to the enable value in response to a wakeup control; and
 - a processing core configured to operate based on the gated clock signal, the processing core providing the disable control to the polling module during an operation.
9. The semiconductor memory device of claim 8, wherein the processing core is configured to execute first instructions during the operation, the first instructions cause the processing core to provide the disable control.
 10. The semiconductor memory device of claim 8, wherein the polling module comprises a storage element configured to:
 - be in a first state in response to the disable control; and
 - be in a second state in response to the wakeup control.
 11. The semiconductor memory device of claim 9, wherein the wakeup control includes signals from a plurality of wakeup sources, and the polling module is configured to output a wakeup status that is indicative of a wakeup source from the plurality of wakeup sources.
 12. The semiconductor memory device of claim 11, wherein the polling module is configured to output the wakeup status that is indicative of the wakeup source from the plurality of wakeup sources based on a priority sequence.
 13. The semiconductor memory device of claim 11, wherein the processing core is configured to execute second instructions associated with the wakeup status.
 14. The semiconductor memory device of claim 8, wherein the polling module is configured to set, based on a factory setup parameter, the clock enable signal to the enable value regardless of the disable control.
 15. A method for power saving in a microcontroller unit (MCU), comprising:
 - receiving, by a polling module of the MCU, a disable control from a processing core of the MCU;
 - disabling, by the polling module of the MCU and in response to the disable control, signal transitions in a gated clock signal that is provided to the processing core of the MCU; and
 - enabling, by the polling module of the MCU, the signal transitions in the gated clock signal in response to a wakeup control.
 16. The method of claim 15, further comprising:
 - generating, by the processing core of the MCU executing first instructions, the disable control.
 17. The method of claim 15, further comprising:
 - setting, a storage element in the polling module of the MCU to a first state in response to the disable control;
 - clearing, the storage element in the polling module of the MCU to a second state in response to the wakeup control; and
 - controlling a clock gating circuit to generate the gated clock signal based on the storage element in the polling module of the MCU.
 18. The method of claim 16, wherein the wakeup control includes signals from a plurality of wakeup sources, and the method further comprises:
 - outputting a wakeup status that is indicative of a wakeup source from the plurality of wakeup sources based on a priority sequence.

19. The method of claim 18, wherein the processing core is configured to execute second instructions associated with the wakeup status.

20. The method of claim 15, further comprising:
enabling, by the polling module of the MCU, the signal 5
transitions in the gated clock signal based on a factory
setup parameter, regardless of the disable control.
