A switching power supply includes: a switching type power supply circuit that converts an input voltage to generate an output voltage; and a control IC that executes feedback control that, based on a differential voltage between a target voltage and the output voltage from the power supply circuit, controls a switching element of the power supply circuit and causes the output voltage from the power supply circuit to converge to the target voltage. The control IC sets the target voltage for each predetermined period based on a value obtained by adding a preset value to the output voltage at a time of startup of the power supply circuit. Provided with this operation is a switching power supply that can precisely reduce an overshoot of the output voltage at the time of startup.

SWITCHING POWER SUPPLYCROSS-REFERENCE TO RELATED
APPLICATION

This application is a continuation application of International Application PCT/JP2014/080219, filed on Nov. 14, 2014, and designating the U.S., the entire contents of which are incorporated herein by reference.

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a switching power supply.

2. Description of the Related Art

Japanese Patent Application Laid-open No. 2008-301581 discloses a switching type DC-DC converter having a soft-start circuit as a conventional switching power supply, for example. This soft-start circuit, until an output voltage of the converter reaches a set voltage, compares a voltage by a capacitor for soft start and a dividing resistor for soft start with a reference voltage that is equal to a voltage by a dividing resistor for output voltage detection when the output voltage is the set voltage, and controls a duty period of an output transistor.

Although the switching type DC-DC converter having the soft-start circuit reduces an overshoot of the output voltage at startup by being configured as described above, a more precise overshoot reduction is demanded, for example.

SUMMARY OF THE INVENTION

The present invention has been made in view of the above circumstances, and an object thereof is to provide a switching power supply that can precisely reduce an overshoot of an output voltage at startup.

In order to achieve the above mentioned object, a switching power supply according to one aspect of the present invention includes a switching type power supply circuit configured to convert an input voltage to generate an output voltage; and a control integrated circuit configured to execute feedback control that, based on a differential voltage between a target voltage and the output voltage from the power supply circuit, controls a switching element of the power supply circuit and causes the output voltage from the power supply circuit to converge to the target voltage, wherein the control integrated circuit sets the target voltage for each predetermined period based on a value obtained by adding a preset value to the output voltage at a time of startup of the power supply circuit.

According to another aspect of the present invention, in the switching power supply, it is possible to configure that when a value obtained by adding the preset value to the output voltage is lower than a maximum voltage of the target voltage in the past set during this-time startup at the time of startup of the power supply circuit, the control integrated circuit sets the maximum voltage as the target voltage.

According to still another aspect of the present invention, in the switching power supply, it is possible to configure that the control integrated circuit makes the preset value variable.

According to still another aspect of the present invention, in the switching power supply, it is possible to configure that the control integrated circuit makes the preset value relatively larger when a differential voltage between a predetermined final target voltage and the output voltage is relatively larger, and makes the preset value relatively

2

smaller when the differential voltage between the final target voltage and the output voltage is relatively smaller.

According to still another aspect of the present invention, in the switching power supply, it is possible to configure that the control integrated circuit fixes the target voltage to the final target voltage after the target voltage or the output voltage becomes a predetermined final target voltage.

The above and other objects, features, advantages and technical and industrial significance of this invention will be better understood by reading the following detailed description of presently preferred embodiments of the invention, when considered in connection with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a configuration diagram illustrating a schematic configuration of a switching power supply according to an embodiment;

FIG. 2 is a block diagram illustrating an example of a schematic configuration of a control IC of the switching power supply according to the embodiment;

FIG. 3 is a flowchart illustrating an example of startup control by the control IC of the switching power supply according to the embodiment;

FIG. 4 is a diagram illustrating an example of an output voltage waveform when the startup control by the control IC of the switching power supply according to the embodiment is performed;

FIG. 5 is a diagram illustrating an example of an output voltage waveform when the startup control by the control IC of the switching power supply according to the embodiment is performed; and

FIG. 6 is a diagram illustrating an example of an output voltage waveform when startup control by a control IC of a switching power supply according to a modification is performed.

DETAILED DESCRIPTION OF THE
PREFERRED EMBODIMENTS

The following describes an embodiment according to the present invention in detail with reference to the accompanying drawings. The present invention is not limited by this embodiment. Components in the following embodiment include components that can easily be replaced by those skilled in the art or substantially the same components.

Embodiment

FIG. 1 is a configuration diagram illustrating a schematic configuration of a switching power supply according to the embodiment. FIG. 2 is a block diagram illustrating an example of a schematic configuration of a control IC of the switching power supply according to the embodiment. FIG. 3 is a flowchart illustrating an example of startup control by the control IC of the switching power supply according to the embodiment. FIG. 4 and FIG. 5 are diagrams illustrating an example of an output voltage waveform when the startup control by the control IC of the switching power supply according to the embodiment is performed.

The switching power supply 1 according to the embodiment illustrated in FIG. 1 includes a switching type power supply circuit 2 that converts an input voltage V_{in} to generate an output voltage V_{out} , and a control integrated circuit (IC) 3 that controls a switching element (a transistor 23) of the power supply circuit 2. This switching power

3

supply 1 performs on/off control of the switching element of the power supply circuit 2 by the control IC 3, thereby generating and outputting a stable direct-current voltage from the power supply circuit 2.

The power supply circuit 2 of the present embodiment is a switching type step-down DC-DC converter circuit including a power supply 21, a capacitor (C1) 22, the transistor (Q1) 23 as the switching element, a diode (D1) 24, an inductor (L1) 25, and a capacitor (C2) 26. The power supply 21 is a direct-current power supply, in which a GND terminal is connected to a negative pole, and one end of the capacitor 22 and a drain terminal of the transistor 23 are connected to a positive pole. The capacitor 22 is a smoothing capacitor, in which the GND terminal is connected to the other end. The transistor 23 is an N-channel field effect transistor (FET), in which the positive pole of the power supply 21 is connected to the drain terminal as described above, a cathode of the diode 24 and one end of the inductor 25 are connected to a source terminal, and the control IC 3 is connected to a gate terminal. The diode 24 is a rectifying diode, in which the GND terminal is connected to an anode. To the other end of the inductor 25, one end of the capacitor 26 and an output terminal (an output terminal of the power supply circuit 2) to a load device (an electric instrument consuming electric power) are connected. The capacitor 26 is a smoothing capacitor, in which the GND terminal is connected to the other end. The control IC 3 controls a duty period (an on period) of the transistor 23, whereby the power supply circuit 2 performs voltage conversion of the direct-current input voltage V_{in} applied by the power supply 21 into the direct-current output voltage V_{out} and outputs the output voltage V_{out} to the load device from the output terminal.

The control IC 3 controls a drive of the power supply circuit 2 and is an integrated circuit including an electronic circuit mainly including a well-known microcomputer including a CPU, a ROM, a RAM, and an interface. To the control IC 3, the GND terminal and the gate terminal of the transistor 23 are connected, the output terminal of the power supply circuit 2 is connected via a voltage detection line 4, and the output voltage V_{out} from the power supply circuit 2 is input. The control IC 3 performs feedback control that, based on a differential voltage between a target voltage V_t and the output voltage V_{out} from the power supply circuit 2, controls the transistor 23 as the switching element of the power supply circuit 2 and causes the output voltage V_{out} from the power supply circuit 2 to converge to the target voltage V_t . The control IC 3 computes a controlled variable of the transistor 23 based on the differential voltage between the target voltage V_t and the output voltage V_{out} and controls the transistor 23 based on the controlled variable.

More specifically, the control IC 3 computes the differential voltage between the target voltage V_t and the output voltage V_{out} from the power supply circuit 2 input via the voltage detection line 4. The target voltage V_t is a voltage as a target of the output voltage V_{out} in the feedback control, which is typically determined in accordance with a voltage required by the load device connected to the power supply circuit 2 or the like and is variably set at the startup of the power supply circuit 2 as described below. The control IC 3 computes the controlled variable of the transistor 23 based on the computed differential voltage between the target voltage V_t and the output voltage V_{out} . The controlled variable of the transistor 23 is typically a duty period corresponding to the length of the on period of the transistor 23 as the switching element. The output voltage V_{out} of the power supply circuit 2 becomes relatively larger as the duty

4

period becomes relatively longer and becomes relatively smaller as the duty period becomes relatively shorter. The control IC 3 computes the duty period as the controlled variable of the transistor 23 so that the computed differential voltage between the target voltage V_t and the output voltage V_{out} will be smaller (that is, so that the output voltage V_{out} will converge to the target voltage V_t) by what is called P control, PI control, or PID control. The control IC 3 stores a controlled variable map (or a mathematical model) and the like that specifies a correspondence relation between the differential voltage between the target voltage V_t and the output voltage V_{out} and the duty period as the controlled variable of the transistor 23 in a storage unit and computes the duty period as a target of control from the differential voltage between the target voltage V_t and the output voltage V_{out} using the controlled variable map, for example. Specifically, the control IC 3 makes the duty period relatively longer as the differential voltage between the target voltage V_t and the output voltage V_{out} becomes relatively larger and makes the duty period relatively shorter as the differential voltage becomes relatively smaller. Based on the computed duty period, the control IC 3 generates a pulse-width-modulated PWM signal (a pulse signal) and outputs the PWM signal to the transistor 23 and performs on/off control of the transistor 23 so that the output voltage V_{out} will converge to the target voltage V_t .

The control IC 3 of the present embodiment performs setting so as to increase the target voltage V_t in stages at a time of startup of the power supply circuit 2 and can thereby precisely reduce an overshoot of the output voltage V_{out} at the startup of the power supply circuit 2.

At the time of startup of the power supply circuit 2 is typically a period from a point in time when a startup signal of the power supply circuit 2 is input to the switching power supply 1 or a preset startup condition is satisfied, whereby the startup of the power supply circuit 2 is started, to a point in time when the output voltage V_{out} of the power supply circuit 2 converges to a predetermined final target voltage V_{ft} . The final target voltage V_{ft} is set as a fixed value in advance in accordance with the voltage required by the load device connected to the power supply circuit 2 and is stored in the storage unit.

Specifically, the control IC 3 sets the target voltage V_t based on a value obtained by adding a preset value ΔV_t to the output voltage V_{out} at the time of startup of the power supply circuit 2. The preset value ΔV_t is a value freely set in advance. The overshoot of the output voltage V_{out} at startup tends to occur when the duty period corresponding to the length of the on period of the transistor 23 is relatively longer. In consideration of this point, the preset value ΔV_t is set in advance based on an experiment or the like as a value that does not cause the overshoot owing to an excessively long duty period and is stored in the storage unit. In this example, the preset value ΔV_t is a fixed value.

When the value obtained by adding the preset value ΔV_t to the output voltage V_{out} is lower than a maximum voltage V_{tmax} of the target voltage V_t in the past having been set during this-time startup, at the startup of the power supply circuit 2, the control IC 3 of the present embodiment sets the maximum voltage V_{tmax} as the target voltage V_t . With this operation, the control IC 3 causes the temporarily set target voltage V_t not to decrease at the startup of the power supply circuit 2. The control IC 3 of the present embodiment fixes the target voltage V_t to the final target voltage V_{ft} after the target voltage V_t or the output voltage V_{out} reaches the final target voltage V_{ft} . In other words, the control IC 3 sets the target voltage V_t to the value obtained by adding the preset

5

value ΔV_t to the output voltage V_{out} when the output voltage V_{out} is the final target voltage V_{ft} or less and when the value obtained by adding the preset value ΔV_t to the output voltage V_{out} is less than the final target voltage V_{ft} at the startup of the power supply circuit 2.

The following describes an example of a schematic configuration of the control IC 3 of the present embodiment with reference to the block diagram in FIG. 2.

As illustrated in FIG. 2, the control IC 3 is configured to include a target voltage computing unit 31, a subtracting unit 32, a feedback computing unit 33, and a PWM controller 34 in terms of functional concepts.

The target voltage computing unit 31 computes the target voltage V_t . To the target voltage computing unit 31, the output voltage V_{out} from the power supply circuit 2 is input via the voltage detection line 4. The target voltage computing unit 31 detects the output voltage V_{out} at the start of the startup (immediately before the start of the startup) of the power supply circuit 2 and checks the state of the output voltage V_{out} . The output voltage V_{out} at the start of the startup (immediately before the start of the startup) of the power supply circuit 2 is not limited to 0 V and may be a certain voltage under the influence of a load state of the load device connected to the power supply circuit 2, for example. However, the output voltage V_{out} at the start of the startup (immediately before the start of the startup) of the power supply circuit 2 is typically less than the final target voltage V_{ft} . The target voltage computing unit 31 sets the target voltage V_t based on the value obtained by adding the preset value ΔV_t to the output voltage V_{out} at the startup of the power supply circuit 2. When the value obtained by adding the preset value ΔV_t to the output voltage V_{out} is lower than a maximum voltage V_{tmax} of the target voltage V_t in the past having been set during this-time startup, at the startup of the power supply circuit 2, the target voltage computing unit 31 sets the maximum voltage V_{tmax} as the target voltage V_t . After the target voltage V_t or the output voltage V_{out} reaches the final target voltage V_{ft} , the target voltage computing unit 31 fixes the target voltage V_t to the final target voltage V_{ft} . The target voltage computing unit 31 outputs the target voltage V_t that has been computed and set to the subtracting unit 32.

The subtracting unit 32 computes the differential voltage between the target voltage V_t and the output voltage V_{out} . To the subtracting unit 32, the target voltage V_t is input from the target voltage computing unit 31, and the output voltage V_{out} from the power supply circuit 2 is input via the voltage detection line 4. The subtracting unit 32 computes the differential voltage between the input target voltage V_t and output voltage V_{out} and outputs the computed differential voltage to the feedback computing unit 33.

The feedback computing unit 33 computes the controlled variable (a feedback controlled variable) of the transistor 23 based on the differential voltage between the target voltage V_t and the output voltage V_{out} . To the feedback computing unit 33, the differential voltage between the target voltage V_t and the output voltage V_{out} is input from the subtracting unit 32. The feedback computing unit 33 computes the duty period as the controlled variable of the transistor 23 so that, based on the differential voltage between the input target voltage V_t and output voltage V_{out} , the differential voltage will be smaller by P control, PI control, or PID control (PI control as an example in this example). The feedback computing unit 33 outputs a signal corresponding to the computed duty period to the PWM controller 34.

The PWM controller 34 actually performs on/off control of the transistor 23 in accordance with the duty period as the

6

controlled variable of the transistor 23. To the PWM controller 34, the signal corresponding to the duty period as the controlled variable of the transistor 23 is input from the feedback computing unit 33. The PWM controller 34 generates a PWM signal pulse-width-modulated based on the input signal corresponding to the duty period, outputs the PWM signal to the transistor 23, and performs on/off control of the transistor 23 so that the output voltage V_{out} will converge to the target voltage V_t .

Next, the following describes an example of startup control of the power supply circuit 2 by the control IC 3 with reference to the flowchart in FIG. 3. These control routines are repeatedly executed at a control period (in units of clocks) of a few milliseconds to a few tens of milliseconds.

First, when the startup signal of the power supply circuit 2 is input or the preset startup condition is satisfied, whereby the startup of the power supply circuit 2 is started, the target voltage computing unit 31 of the control IC 3 detects the present output voltage V_{out} (Step ST1).

Next, the target voltage computing unit 31 determines whether soft start control, that is, control to perform setting so as to increase the target voltage V_t in stages is to be performed at the startup of the power supply circuit 2 (Step ST2). The target voltage computing unit 31 may determine the necessity of the soft start control in accordance with an operating state of the entire switching power supply 1, the load state of the load device connected to the power supply circuit 2, or the like, for example; it is basically determined that the soft start control is necessary in this example.

If it is determined that the soft start control is performed (Yes at Step ST2), the target voltage computing unit 31 determines whether the present output voltage V_{out} is the predetermined final target voltage V_{ft} or less (Step ST3).

If it is determined that the present output voltage V_{out} is the final target voltage V_{ft} or less (Yes at Step ST3), the target voltage computing unit 31 computes a value obtained by adding the predetermined preset value ΔV_t to the present output voltage V_{out} and temporarily sets this value as the target voltage V_t (Step ST4).

Next, the target voltage computing unit 31 determines whether the target voltage V_t computed at Step ST4 is less than the final target voltage V_{ft} (Step ST5).

If it is determined that the target voltage V_t computed at Step ST4 is less than the final target voltage V_{ft} (Yes at Step ST5), the target voltage computing unit 31 determines whether the target voltage V_t computed at Step ST4 is the maximum voltage V_{tmax} of the target voltage V_t having been set by the previous control period or more (Step ST6). In other words, with this operation, the target voltage computing unit 31 determines whether the target voltage V_t of the present control period obtained by adding the preset value ΔV_t to the output voltage V_{out} is the maximum voltage V_{tmax} of target voltage V_t in the past having been set during this-time startup or more at the startup of the power supply circuit 2.

If it is determined by the target voltage computing unit 31 that the target voltage V_t computed at Step ST4 is the maximum voltage V_{tmax} of the target voltage V_t having been set by the previous control period or more (Yes at Step ST6), the control IC 3 executes PI control of the transistor 23 based on the value obtained by adding the preset value ΔV_t to the presently set target voltage V_t , or the present output voltage V_{out} in this example (Step ST7), ends the present control period, and shifts to the next control period. In this case, the subtracting unit 32 of the control IC 3 computes a differential voltage between the presently set target voltage V_t and the output voltage V_{out} . The feedback

computing unit 33 of the control IC 3 computes the duty period as the controlled variable of the transistor 23 based on the differential voltage. The PWM controller 34 of the control IC 3 outputs the PWM signal pulse-width-modulated based on the duty period to the transistor 23 and performs on/off control of the transistor 23.

If it is determined that the target voltage V_t computed at Step ST4 is smaller than the maximum voltage V_{tmax} of the target voltage V_t having been set by the previous control period at Step ST6 (No at Step ST6), the target voltage computing unit 31 sets the maximum voltage V_{tmax} as the target voltage V_t (Step ST8) and performs the processing at Step ST7. In this case, the control IC 3 executes PI control of the transistor 23 based on the presently set target voltage V_t , or the maximum voltage V_{tmax} of the target voltage V_t having been set by the previous control period in this example.

If it is determined that the soft start control is not to be performed at Step ST2 (No at Step ST2), if it is determined that the present output voltage V_{out} is larger than the final target voltage V_{ft} at Step ST3 (No at Step ST3), or if it is determined that the target voltage V_t computed at Step ST4 is the final target voltage V_{ft} or more at Step ST5 (No at Step ST5), the target voltage computing unit 31 fixes the target voltage V_t to the final target voltage V_{ft} (Step ST9) and performs the processing at Step ST7. In this case, the control IC 3 executes PI control of the transistor 23 based on the presently set target voltage V_t , or the final target voltage V_{ft} in this example.

FIG. 4 and FIG. 5 illustrate an example of an output voltage waveform when the above startup control is performed by the control IC 3. In FIG. 4 and FIG. 5, the horizontal axis is a time axis by the control period (Time [STEP]), and the vertical axis is a voltage (Voltage [V]).

As illustrated in FIG. 4, the switching power supply 1 configured as described above is set so that the target voltage V_t will increase in stages by each control period by the control IC 3 at the startup of the power supply circuit 2. In the switching power supply 1 of the present embodiment, the value obtained by adding the preset value ΔV_t to the present output voltage V_{out} is set as the target voltage V_t by the control IC 3 at the startup of the power supply circuit 2. With this operation, the switching power supply 1 can prevent the differential voltage between the target voltage V_t and the output voltage V_{out} from being extremely large at the startup of the power supply circuit 2. In this example, the switching power supply 1 can gradually increase the target voltage V_t based on the present output voltage V_{out} by setting the value obtained by adding the preset value ΔV_t to the output voltage V_{out} as the target voltage V_t at the startup of the power supply circuit 2 and can thereby reliably prevent the differential voltage between the target voltage V_t and the output voltage V_{out} from being extremely large. As a result, the switching power supply 1 can relatively reduce the duty period that the transistor 23 is requested to exhibit at the startup of the power supply circuit 2. Consequently, the switching power supply 1 can prevent a phenomenon in which the output voltage V_{out} is extremely large relative to the target voltage V_t , that is, the overshoot from occurring at the startup of the power supply circuit 2. The switching power supply 1 can set a larger value than the present output voltage V_{out} as the target voltage V_t even at the initial stage of startup and can thereby improve rising of the target voltage V_t and the output voltage V_{out} and quickly start up the power supply circuit 2. After the target voltage V_t is fixed to the final target voltage V_{ft} , the output voltage V_{out} converges to the target voltage V_t at a point in time t_{11} , and

the startup of the power supply circuit 2 completes, whereby the switching power supply 1 can output a stable output voltage V_{out} . In the example in FIG. 4, a startup period T_1 of the power supply circuit 2 is the period from the point in time when the startup of the power supply circuit 2 is started to the point in time t_{11} when the output voltage V_{out} of the power supply circuit 2 converges to the target voltage V_t (=the final target voltage V_{ft}).

In the switching power supply 1, when the value obtained by adding the preset value ΔV_t to the output voltage V_{out} is lower than the maximum voltage V_{tmax} of the target voltage V_t in the past having been set during this-time startup, at the startup of the power supply circuit 2, the maximum voltage V_{tmax} is set as the target voltage V_t by the control IC 3. Consequently, even when the output voltage V_{out} temporarily decreases owing to a sudden rise of the load of the load device connected to the power supply circuit 2 or the like, for example, as illustrated in from a point in time t_{21} to a point in time t_{22} in FIG. 5, the switching power supply 1 can cause the temporarily set target voltage V_t not to decrease.

The switching power supply 1 of the present embodiment controls the duty period that the transistor 23 is requested to exhibit by the computation in the control IC 3 to perform startup control of the power supply circuit 2 as described above and can thereby reduce the influence of parts characteristic variations compared with a case in which similar functionality is achieved by an analog circuit, for example, whereby the overshoot of the output voltage V_{out} at the startup of the power supply circuit 2 can precisely be reduced. The switching power supply 1 can reduce the number of components compared with a case in which similar functionality is achieved by an analog circuit, for example, and can thereby reduce a component mounting area and miniaturize the device. Furthermore, the switching power supply 1 can achieve a function of soft start control (startup control) by the computation in the control IC 3 without using parts such as capacitors and resistors and can thereby practically prevent deterioration of parts related to the function of the soft start control and can be operated constantly with a similar level of accuracy. In other words, the switching power supply 1 can prevent the influence of changes in parts characteristics caused by deterioration over time and can thereby precisely reduce the overshoot even when being used for a long term. Even when specifications required for the switching power supply 1 are changed, the switching power supply 1 can adapt to the required specifications by altering the control IC 3 in terms of software without altering parts, thereby making design alterations easy.

The switching power supply 1 described above includes the switching type power supply circuit 2 that converts the input voltage V_{in} to generate the output voltage V_{out} and the control IC 3 that executes feedback control that, based on the differential voltage between the target voltage V_t and the output voltage V_{out} from the power supply circuit 2, controls the transistor 23 of the power supply circuit 2 and causes the output voltage V_{out} from the power supply circuit 2 to converge to the target voltage V_t . The control IC 3 sets the target voltage V_t based on the value obtained by adding the preset value ΔV_t to the output voltage V_{out} at the startup of the power supply circuit 2. Consequently, the switching power supply 1 performs startup control of the power supply circuit 2 by the computation in the control IC 3, whereby the influence of parts characteristic variations can be reduced, and the overshoot of the output voltage V_{out} can precisely

be reduced at the startup of the power supply circuit 2. Consequently, the switching power supply 1 can improve reliability.

Furthermore, in the switching power supply 1 described above, when the value obtained by adding the preset value ΔV_t to the output voltage V_{out} is lower than the maximum voltage V_{max} of the target voltage V_t in the past having been set during this-time startup, at the startup of the power supply circuit 2, the control IC 3 sets the maximum voltage V_{max} as the target voltage V_t . Consequently, even when the output voltage V_{out} temporarily decreases, for example, the switching power supply 1 can cause the temporarily set target voltage V_t not to decrease and can thereby prevent the influence of a sudden drop of the output voltage V_{out} or the like and smoothly complete startup even when startup is performed with the target voltage V_t being set in accordance with the output voltage V_{out} .

Furthermore, in the switching power supply 1 described above, after the target voltage V_t or the output voltage V_{out} reaches the predetermined final target voltage V_{ft} , the control IC 3 fixes the target voltage V_t to the final target voltage V_{ft} . Consequently, the switching power supply 1 can output a stable output voltage V_{out} after the output voltage V_{out} converges to the target voltage V_t (the final target voltage V_{ft}). Even when, in relation to the final target voltage V_{ft} , the preset value ΔV_t is not set to magnitude that makes the target voltage V_t specified by the sum of the output voltage V_{out} and the preset value ΔV_t exactly match the final target voltage V_{ft} , and the target voltage V_t specified by the sum of the output voltage V_{out} and the preset value ΔV_t exceeds the final target voltage V_{ft} , for example, the switching power supply 1 can fix the target voltage V_t to the final target voltage V_{ft} when the target voltage V_t is about to exceed the final target voltage V_{ft} . Also in this regard, the switching power supply 1 can reliably output a stable output voltage V_{out} .

The switching power supply according to the embodiment of the present invention described above is not limited to the embodiment described above, and various alterations can be made within the scope described in the claims.

Although the control IC 3 is described with the preset value ΔV_t as a fixed value in the above description, the preset value ΔV_t may be variable. The control IC 3 may alter the preset value ΔV_t based on an external environment of the switching power supply 1, a load condition of the load device connected to the power supply circuit 2, or the like, for example. The control IC 3 can also freely set the startup time of the power supply circuit 2 by appropriately altering this preset value ΔV_t , for example. In other words, this switching power supply 1 can easily alter the startup time of the power supply circuit 2 to a desired time by altering the preset value ΔV_t in terms of software, whereby manufacturing costs can also be reduced.

FIG. 6 is a diagram illustrating an example of an output voltage waveform when startup control by a control IC of a switching power supply according to a modification is performed.

The control IC 3 of the switching power supply 1 according to the present modification computes and sets the preset value ΔV_t based on a differential voltage between the final target voltage V_{ft} and the output voltage V_{out} as an example. As illustrated in FIG. 6, the target voltage computing unit 31 of the control IC 3 according to the present modification makes the preset value ΔV_t relatively larger when the differential voltage between the final target voltage V_{ft} and the output voltage V_{out} is relatively larger and makes the preset value ΔV_t relatively smaller when the differential

voltage is relatively smaller. In this example, the target voltage computing unit 31 sets a preset value ΔV_{t2} immediately before the completion of startup at which the differential voltage between the final target voltage V_{ft} and the output voltage V_{out} is relatively smaller to a value smaller than a preset value ΔV_{t1} at the initial stage of startup at which the differential voltage is relatively larger. In this case, the target voltage computing unit 31 may make the preset value ΔV_t in the period from the preset value ΔV_{t1} to the preset value ΔV_{t2} decrease in stages based on the differential voltage between the final target voltage V_{ft} and the output voltage V_{out} .

In this case, the switching power supply 1 according to the modification can make the preset value ΔV_t at the initial stage of startup (ΔV_{t1}) relatively larger to the extent that no overshoot occurs and make the preset value ΔV_t immediately before the completion of startup (ΔV_{t2}) relatively smaller, whereby the overshoot can reliably be reduced while improving the rising of the output voltage V_{out} and quickly starting up the power supply circuit 2. In the example in FIG. 6, a startup period T_2 from the point in time when the startup of the power supply circuit 2 is started to a point in time t_{31} when the output voltage V_{out} of the power supply circuit 2 converges to the target voltage V_t (=the final target voltage V_{ft}) is relatively shorter than the startup period T_1 (refer to FIG. 4).

Although described as the switching type step-down DC-DC converter circuit in the above description, the power supply circuit 2 is not limited to this example and may be a switching type step-up DC-DC converter circuit or another circuit including a switching element, for example. Although described as including the power supply 21 as a direct-current power supply, the power supply circuit 2 is not limited to this example, may include an input terminal to which the input voltage V_{in} is supplied from another power supply circuit in place of the power supply 21, and may be incorporated into part of an AC-DC converter circuit, for example.

Although it is described that, when the value obtained by adding the preset value ΔV_t to the output voltage V_{out} is lower than the maximum voltage V_{max} of the target voltage V_t in the past having been set during this-time startup, at the startup of the power supply circuit 2, the control IC 3 sets the maximum voltage V_{max} as the target voltage V_t , this is not limiting.

Other than the preset value ΔV_t , this switching power supply 1 can also alter the final target voltage V_{ft} , the controlled variable map that specifies the correspondence relation between the differential voltage between the target voltage V_t and the output voltage V_{out} and the duty period as the controlled variable of the transistor 23, a feedback gain used in P control, PI control, PID control, or the like, and change characteristics of current and voltage, for example, in terms of software and can thereby make fine adjustments easily.

The switching power supply according to the present invention performs startup control of the power supply circuit by the computation in the control IC, thereby producing the effect of reducing the influence of parts characteristic variations and precisely reducing the overshoot of the output voltage at startup, for example.

Although the invention has been described with respect to specific embodiments for a complete and clear disclosure, the appended claims are not to be thus limited but are to be construed as embodying all modifications and alternative constructions that may occur to one skilled in the art that fairly fall within the basic teaching herein set forth.

11

What is claimed is:

1. A switching power supply comprising:

a switching type power supply circuit configured to convert an input voltage to generate an output voltage; and

a control integrated circuit configured to execute feedback control that, based on a differential voltage between a target voltage and the output voltage from the power supply circuit, controls a switching element of the power supply circuit and causes the output voltage from the power supply circuit to converge to the target voltage, wherein

the control integrated circuit sets the target voltage for each predetermined period based on a value obtained by adding a preset value to the output voltage at a time of startup of the power supply circuit,

wherein, when a value obtained by adding the preset value to the output voltage is lower than a maximum voltage of the target voltage in the past set during this-time startup at the time of startup of the power supply circuit, the control integrated circuit sets the maximum voltage as the target voltage.

2. The switching power supply according to claim 1, wherein

the control integrated circuit makes the preset value variable.

12

3. The switching power supply according to claim 2, wherein

the control integrated circuit makes the preset value relatively larger when a differential voltage between a predetermined final target voltage and the output voltage is relatively larger, and makes the preset value relatively smaller when the differential voltage between the final target voltage and the output voltage is relatively smaller.

4. The switching power supply according to claim 3, wherein

the control integrated circuit fixes the target voltage to the final target voltage after the target voltage or the output voltage becomes a predetermined final target voltage.

5. The switching power supply according to claim 2, wherein

the control integrated circuit fixes the target voltage to the final target voltage after the target voltage or the output voltage becomes a predetermined final target voltage.

6. The switching power supply according to claim 1, wherein

the control integrated circuit fixes the target voltage to the final target voltage after the target voltage or the output voltage becomes a predetermined final target voltage.
